3 **Abstract.** From 2 to 5 UT on 14 November, 2012, the Van Allen Probes
4 observed repeated particle flux dropouts during the main phase of a geomag-
5 netic storm as the satellites traversed the post-midnight to dawnside inner
6 magnetosphere. Each flux dropout corresponded to an abrupt change in the
7 magnetic topology, i.e., from a more dipolar configuration to a configuration
8 with magnetic field lines stretched in the dawn-dusk direction. Geosynchronous
9 GOES spacecraft located in the dusk and near-midnight sectors and the LANL
10 constellation with wide local time coverage also observed repeated flux dropouts
11 and stretched field lines with similar occurrence patterns to those of the Van
12 Allen Probe events. THEMIS recorded multiple transient abrupt expansions
13 of the evening-side magnetopause $\sim 20\text{--}30$ min prior to the sequential Van
14 Allen Probes observations. Ground-based magnetograms and all sky images
15 demonstrate repeatable features in conjunction with the dropouts. We com-
16 bine the various in-situ and ground-based measurements to define and un-
17 derstand the global spatiotemporal features associated with the dropouts ob-

18 served by the Van Allen Probes. We discuss various proposed hypotheses for
19 the mechanism that plausibly caused this storm-time dropout event as well
20 as formulate a new hypothesis that explains the combined in-situ and ground-
21 based observations: the earthward motion of magnetic flux ropes contain-
22 ing lobe plasmas that form along an extended magnetotail reconnection line
23 in the near-Earth plasma sheet.

Greenbelt, Maryland 20771, USA

1. Introduction

24 When the interplanetary magnetic field (IMF) turns and remains southward for an
25 extended period of time, substantial disturbances of the Earth's magnetosphere, called
26 geomagnetic storms occur. Major disturbances typically observed during the main phase
27 of geomagnetic storms include strong convection of plasmas from the magnetotail to the
28 inner magnetosphere and resultant ring-current injection which decreases the background
29 magnetic field strength, as quantitatively estimated by the disturbance storm time (Dst)
30 geomagnetic index, i.e., a measure of the averaged deviation of H (north-south) component
31 of the magnetic field near the Earth's equator. The recovery phase, during which the value
32 of the Dst index gradually returns to its pre-storm level, is due to loss of ring-current ions
33 via charge exchange with the neutral exosphere and/or loss to the magnetopause.

34 In conjunction with geomagnetic storms, energetic electron observations in the radia-
35 tion belt have shown that the significant decrease in flux during the storm main phase is
36 followed often by a more gradual increase during the recovery phase. Theoretical and ob-
37 servational studies suggest that during the main phase of a geomagnetic storm a build-up
38 of the ring current drives outward radial motion of the electron drift paths to conserve
39 the third adiabatic invariant, i.e., the magnetic flux encircled by a particle's drift orbit.
40 Conservation of the first adiabatic invariant, i.e., the magnetic moment of a gyrating par-
41 ticle subsequently decreases the electron energy flux. This Dst effect, therefore, describes
42 the adiabatic dynamics of trapped radiation belt electrons [*Dessler and Karplus, 1961*;

²The Goddard Planetary Heliophysics

43 *McIlwain*, 1966]. When the fluxes in dropout events often do not return to pre-storm flux
44 levels, there must be real losses via non-adiabatic processes [e.g., *Li et al.*, 1997; *Kim and*
45 *Chan*, 1997; *Onsager et al.*, 2002; *Green et al.*, 2004].

46 Loss mechanisms include particle precipitation to the atmosphere and loss to the mag-
47 netopause. Atmospheric loss of energetic electrons has been attributed to resonant wave-
48 particle interactions between radiation belt electrons and a variety of plasma waves, such
49 as whistler-mode chorus waves, plasmaspheric hiss, and electromagnetic ion cyclotron
50 (EMIC) waves. Whistler-mode chorus waves are distributed over a broad region from mid-
51 night via dawn to noon. Plasmaspheric hiss waves are mostly confined within the dense
52 plasmasphere and within dayside plasmaspheric plumes. EMIC waves are enhanced in
53 the plume and on the dusk-side plasmopause. (See *Thorne* [2010] and references therein.)

54 These waves facilitate pitch angle scattering of electrons into the loss cone, leading to
55 precipitation to the atmosphere [e.g., *Millan and Thorne*, 2007 for a review of loss mecha-
56 nisms] on time scales of hours (in association with EMIC waves that preferentially resonate
57 with > 0.5 MeV electrons) to day(s) (whistler mode chorus) [*Albert*, 2003; *Meredith et al.*,
58 2003; *Summers and Thorne*, 2003; *Albert*, 2005; *Horne et al.*, 2005; *Thorne et al.*, 2005].

59 EMIC waves also resonate with ions, leading to ring current proton precipitation via the
60 scattering of protons into the loss cone [e.g., *Kozyra et al.*, 1997; *Jordanova et al.*, 2001;
61 *Khazanov et al.*, 2002].

62 More recently, the inward motion of the magnetopause (i.e., compression of the day-
63 side magnetosphere) caused by, for example, the arrival of interplanetary shocks and/or
64 pressure pulses at Earth has been found to result in dropouts of the outer radiation belt

Institute, University of Maryland, Baltimore

65 electrons on open drift paths that were closed before the magnetopause motion [*Des-*
66 *orgher et al.*, 2000]. These magnetopause losses not only affect those electrons that drift

67 into the magnetopause but also promote outward radial diffusion via the inward radial
68 gradients created by these losses, producing losses of relativistic electrons, and, as a re-
69 sult, significantly depleting outer belt fluxes on time scales of hours [*Shprits et al.*, 2006].
70 Numerical and observational studies have shown that the combined effects of outward
71 transport and loss to the magnetopause may act as a dominant loss mechanism, causing
72 energy-dependent dropouts throughout the radiation belt on a time scale of a few hours
73 [*Nishimura et al.*, 2007; *Kim et al.*, 2008; *Ukhorskiy and Sitnov*, 2008; *Loto'aniu et al.*,
74 2010; *Shprits et al.*, 2012; *Turner et al.*, 2012].

75 Mechanisms providing replenishment of energetic particles include enhancements of the
76 flux by radial transport or internal energization of trapped drifting electron to $>$ MeV en-
77 ergy level through resonant interaction with waves such as ULF, VLF, and whistler-mode
78 chorus waves by violation of the adiabatic invariants [*Rostoker et al.*, 1998; *Elkington*
79 *et al.*, 2003; *Meredith et al.*, 2003; *O'Brien et al.*, 2003; *Horne et al.*, 2005; *Loto'aniu*
80 *et al.*, 2006, 2010; *Reeves et al.*, 2013; *Thorne et al.*, 2013]. Another mechanism is rapid
81 acceleration of lower-energy seed plasma sheet populations injected into the inner mag-
82 netosphere as a consequence of magnetic reconnection related to substorm phenomena
83 [*Meredith et al.*, 2001, 2006].

84 During the main phase of an intense geomagnetic storm (minimum Dst = -108 nT) on
85 14 November, 2012, abrupt repeated dropouts of both thermal and relativistic populations
86 were observed by NASA's twin spacecraft of the Van Allen Probes, drawing wide atten-
87 tion from the magnetospheric physics community to the need to understand the cause and
88 phenomenological features of the sudden energy-independent dropouts. Various groups
89 sought to model the spatial and temporal observations of the event, reproducing the alter-

90 nating sequences of nominal and dropout intervals that result from sequential crossings of
91 an open-closed boundary [*MacDonald et al.*, 2013; *Glocer et al.*, 2013]. *Moya et al.* [2014,
92 submitted to *J. Geophys. Res.*] reported different wave amplitude levels and magnetic
93 field orientations during the quiet and disturbed/dropout intervals, showing the presence
94 of weak kinetic turbulence which dissipates the energy associated with the intermittent
95 discontinuities in the magnetic field during the main phase of the storm.

96 In this paper, we incorporate in-situ measurements from multi-point spacecraft and
97 ground-based observations to define and understand the global spatiotemporal features
98 associated with the dropouts observed by the Van Allen Probes. Our synthesized anal-
99 yses allow us to formulate a new hypothesis for the mechanism that caused this abrupt
100 repeated dropout event. The following section presents a brief description of instrumenta-
101 tions we used in this study. In Section 3 we provide an overview of the event detected by
102 the Van Allen Probes, GOES, LANL, and Geotail spacecraft. Using THEMIS measure-
103 ments of the dayside magnetopause and ground-based observations, we explore the global
104 and temporal features of the magnetic disturbances in association with the particle flux
105 dropouts (Section 4). Section 5 discusses how this event is related to the magnetospheric
106 configuration and dynamics in response to strong external (interplanetary) drivers, and
107 explore various hypotheses proposed for the cause of this storm-time dropout event as well
108 as formulates a new hypothesis, i.e., magnetic flux bundles repeatedly passing those mul-
109 tiple spacecraft, based on the combined in-situ and ground-based observations. Section 6
110 presents a summary and conclusions.

2. Instrumentation

111 We used spacecraft and ground-based measurements in this study. In-situ measure-
112 ments were from the Van Allen Probes (formerly known as the Radiation Belt Storm
113 Probes–RBSP A and B [*Kessel et al.*, 2013; *Mauk et al.*, 2013], terms we will use here-
114 inafter for brevity), the Time History of Events and Macroscale Interactions (THEMIS)
115 spacecraft [*Angelopoulos*, 2008], the geostationary satellite system (GOES) [*Singer et al.*,
116 1996; *Onsager et al.*, 1996], and the Los Alamos National Laboratory (LANL) instrument
117 [*Reeves et al.*, 1997].

118 High time-resolution (64 vectors/s) DC magnetic field measurements are obtained from
119 the magnetometer instrument, the Electric and Magnetic Field Instrument Suite and
120 Integrated Science (EMFISIS) [*Kletzing et al.*, 2013] onboard the Van Allen Probes.
121 Plasma data are obtained from the three instruments of the Radiation Belt Storm
122 Probes-Energetic Particle Composition and Thermal Plasma (RBSP-ECT) instrument
123 suite [*Spence et al.*, 2013]: the Helium, Oxygen, Proton, and Electron (HOPE) mass
124 spectrometer [*Funsten et al.*, 2013] measuring electron and ion flux distributions over
125 an entire solid angle on alternating spacecraft spins in the energy range of ~ 1 eV–52
126 keV and distinguishing three ion species, H^+ , He^+ , and O^+ ; the Magnetic Electron Ion
127 Spectrometer (MagEIS) [*Blake, J. B. et al.*, 2013] having one low-energy (20–240 keV),
128 two medium-energy (80–1200 keV), and a high-energy (800–4800 keV) spectrometers; the
129 **Relativistic Electron and Proton Telescope (REPT) energetic particle instrument** [*Baker*
130 ***et al.*, 2012**] measuring high-energy electrons of energy range from a few to >10 MeV.
131 Magnetic field measurements aboard THEMIS were made by the Fluxgate Magnetometer
132 (FGM) [*Auster et al.*, 2008] and particle fluxes including onboard plasma moments come

133 from the Electrostatic Analyzer (ESA) with 3 s time cadence [McFadden *et al.*, 2008]. We
134 also use magnetic field and electron flux measurements from the Magnetometer and the
135 Energetic Particle Sensor (EPS) onboard three GOES-13, 14, and 15 spacecraft [described
136 for earlier satellite series in Singer *et al.*, 1996; Onsager *et al.*, 1996] as well as electron flux
137 measurements from the synchronous orbit particle analyzer (SOPA) instruments on six
138 LANL geosynchronous spacecraft [Belian *et al.*, 1992; Reeves *et al.*, 1997]. Ground mea-
139 surements were from THEMIS All-Sky Imager (ASI) [Mende *et al.*, 2008], all-sky cameras
140 at the Sodankylä station (SOD) in Finland, and magnetometers at the stations located
141 over the northern America and Europe.

3. Observations of abrupt particle flux dropouts

3.1. The Van Allen Probes observations

142 From 0100 UT to 0600 UT on 14 November, 2013, during an interval in which the
143 IMF was strongly southward (to be discussed in Section 4.3), the two identical Van Allen
144 Probes observed repeated particle flux dropouts as they passed through the post-midnight
145 to dawnside inner magnetosphere [see Figure 1 showing spacecraft locations in Geocentric
146 Solar Magnetospheric (GSM) coordinates each hour from 0100 UT (large triangle) to
147 0600 UT]. Figure 2 shows the Van Allen Probes observations between 0100 and 0630 UT.
148 Panels (a-c) present the (x, y, z) components of the magnetic field for RBSP-A (blue) and
149 RBSP-B (red) and (d, e) the electron flux spectrogram measured by the ECT/MagEIS
150 instrument aboard RBSP-A and RBSP-B, respectively.

151 Both RBSP-A and B observed repeated abrupt dropouts in particle flux (Figure 2d and
152 e), as bounded by pairs of dot-dashed vertical lines. The dropouts are seen for ions of all
153 species (Figure 3b-d) and for both thermal and energetic electrons (Figure 2d and Figure

154 3e, f) measured by ECT/HOPE, ECT/MagEIS, ECT/REPT, and RBSPICE. Note that
155 the enhanced fluxes of low-energy ions (below a few hundred eV in 3b and c) observed
156 by HOPE are due to the effects of spacecraft potential, which is often elevated during
157 storm times and accelerates these low-energy particles into the detector. The fact that
158 the sudden reductions in particle flux immediately recover during undisturbed periods
159 following the sequential dropouts is an indication of transient or local phenomena, unlike
160 the long-term storm-associated loss of particles mentioned in Section 1.

161 There are intense magnetic-field variations during the disturbed (dropout) times (Fig-
162 ure 2a-c): B_x and B_z decrease in magnitude while B_y increases along the $-y$ direction,
163 characterizing events by large magnetic strength. Note that (1) prior to the event, e.g.,
164 during $\sim 0130\text{--}\sim 0155$ UT, the magnetic field measurements ($\sqrt{B_x^2 + B_y^2} > |B_z|$) indicate
165 an unusually highly stretched status of the inner magnetosphere, (2) each dropout is often
166 preceded by a small dip in B_x (arrows in Figure 2a) and ends with a sharp transient B_z
167 increase (arrows in Figure 2c) except the first dropout occurring at ~ 0200 UT where B_z
168 profiles are bipolar rather than transiently peaked over an extended period of the dropout
169 signature starting from ~ 0155 UT (marked by another dot-dashed vertical line associated
170 with the first dropout), indicated by a precursive reduction in the electron flux (Figure
171 2d), to ~ 0205 UT.

172 RBSP-B follows the trajectory of RBSP-A (Figure 1), missing the first dropout, yet
173 observing a final dropout at ~ 0507 UT that was not detected by RBSP-A. RBSP-B
174 also observed a weak flux depression from 0543:15 UT to 0551:30 UT, during which
175 the magnetic field varies in similar patterns to those for intense dropouts. Having each

176 encountered five abrupt dropouts (marked by red shading at the bottom of Figure 2), the
177 two Van Allen Probes subsequently headed towards perigee.

3.2. The GEO observations

178 GOES-13, 14, 15 traced geosynchronous orbits (GEO) through the dusk and near-
179 midnight sectors from 0100 to 0600 UT (Figure 1). Figure 4 shows the magnetic field
180 and electron and proton particle fluxes measured by the three probes. Simultaneous
181 changes in the magnetic field and particle flux are seen more clearly towards dusk and
182 farther from the near-midnight sector. In particular, the number of those intermittent
183 changes and their periodicity observed by GOES-15 (bottom three panels in Figure 4),
184 residing mostly in the dusk sector during the event, shows some similarity to the Van Allen
185 Probes observations. Noteworthy differences between the GOES-15 and the Van Allen
186 Probes measurements are (1) although similar features associated with flux dropouts are
187 detected both in the dawn (Van Allen Probes) and the dusk (GOES-15) sectors, there is
188 no one-to-one correspondence and they are not often coincident, i.e., GOES-15 observes
189 the second to fifth dropouts 9 – 15 min earlier than those at the Van Allen Probes (see
190 Table 1) ; (2) electron and proton particle flux dropouts sometimes do not correspond
191 (indicated by vertical magenta lines), and decreases are often bounded by flux increases
192 (see dot-dashed vertical lines in Figure 4); (3) patterns of the magnetic-field disturbances
193 during the dropout intervals also vary, but the most common are enhancements along the
194 anti-earthward and northward directions. GOES-15 also often displays a gradual change
195 in the magnetic field prior to the time of maximized dropouts unlike the sudden changes
196 in magnetic morphology observed by the Van Allen Probes. The gradual change before
197 the event peaks, which is followed by a fast recovery (for example, see the magnetic field

198 variations around the dropout occurring at ~ 0255 UT) possibly indicates a developmental
199 phase before the onset of the dynamics causing flux dropouts or a precursor to remotely
200 approaching structures associated with dropouts.

201 Additional GEO observations providing further local time coverage are obtained from
202 the LANL constellation (see Figure 1). Figure 5 shows that the six LANL spacecraft also
203 encountered intermittent electron flux dropouts and simultaneous reductions in proton
204 flux (not shown). Three noticeable dropouts are detected by LANL-97A, LANL-04A,
205 and LANL-02A, sequentially (red arrows in Figure 5), indicating azimuthal propagation.
206 LANL-01A and 1991-080, situated in the afternoon sector and slightly behind the dusk
207 terminator during 0150–0420 UT and 0300–0530 UT, respectively, experienced prolonged
208 periods of flux reduction. Interestingly, although 1991-080 was located close to GOES-
209 15, the two spacecraft measured remarkably different particle flux variations. We find
210 that the magnetic latitudes of LANL-01A and 1991-080 obtained from the T96 model
211 [*Tsyganenko, 1995*] range between -10° and -30° during the extended dropout intervals
212 [*MacDonald et al., 2013*], compared to that of GOES-15, which falls within 10° of the
213 magnetic equator. These latitudinal differences between GOES and LANL observations
214 will be discussed further when constructing the global features of these events in Section
215 4.

3.3. The Geotail observations

216 Geotail traversed the outer dawn-side magnetosphere toward the morning magnetopause
217 during the period of interest (Figure 1). Figure 6 shows (a) the magnetic field, (b) energetic
218 electron flux, (c, d) energetic ion flux, (e, f) thermal ion and electron flux. [There was
219 no data available between 0430 UT and 0630 UT.] Geotail made a short excursion to the

220 magnetosheath from ~ 0315 to ~ 0345 UT, as indicated by a southward B_z component
221 (Figure 6a), a cold dense low-energy (a few hundreds eV or below) populations, and the
222 sharp decrease in energetic ion populations (Figure 6e, f). Interestingly, Geotail also
223 observed repeated losses of both thermal and energetic particle flux bounded by pairs of
224 dot-dashed vertical lines at ~ 0202 , 0300 , and 0415 UT. Although less clear than in the
225 case of the Van Allen Probes observations, the magnetic strength also increases during
226 these reduced flux intervals, each of which is marked by an enhancement in the dawnward
227 ($-B_y$) component of the magnetic field.

4. Propagation of signatures associated with flux dropouts

4.1. Timing analyses of flux-dropout structures

228 Although the flux dropouts/reductions and corresponding magnetic topology changes
229 occur intermittently with comparable periodicity at many magnetospheric locations, their
230 occurrence patterns generally show no clear one-to-one correspondences. We combined all
231 in-situ measurements available for the event, presented in Section 2, to see if any prop-
232 agation signatures are revealed. Table 1 lists the observation times for each spacecraft
233 detection of the onset time (upper number) and the peak flux depression time (lower
234 number) of the series of flux reduction. Times of weak flux reductions are in paren-
235 theses. A thick vertical line separates post-midnight/dawn-side observation times from
236 pre-midnight/dusk-side ones.

237 The first dropout around at 0200 UT is observed, in sequence, by LANL-97A, RBSP-A,
238 Geotail, LANL-04A, and LANL-02A, i.e., from post-midnight to dawn and towards morn-
239 ing sector as indicated by spacecraft locations in Figure 1. Later dropouts are, in general,
240 consistent with this trend, as was shown from three LANL (LANL-97A, LANL-04A, and

LANL-02A) observations in Section 3.2. However, the third dropout was measured by LANL-97A at ~ 0336 UT, about 0.5 (2.0) min later than RBSP-A (B). During the third event, LANL-97A was located azimuthally closer to midnight but radially outward from the two probes, suggesting that this dropout signature propagated slightly outward in the radial direction in the dawn sector together with its azimuthal motion. [The underlying assumptions are that the dropout signatures propagate like a planar discontinuity and propagation normals approximately lie on the equatorial plane.] Figure 2, in fact, demonstrates that RBSP-B, located azimuthally closer to midnight in local time and/or more earthward than RBSP-A during the first to third dropout times, detected each event ~ 1 –5 minutes earlier than RBSP-A.

Pre-midnight/dusk observations from GOES-13, 14, and 15, LANL 1991-080 and 1994-084 provide less evidence for propagating features. However, the fourth dropout at ~ 0400 UT, observed sequentially by 1994-084, GOES-13, 14, and 15 (and/or 1991-080 observing an extended event until 0422 UT) also suggests azimuthal propagation away from midnight.

These timing analyses in general indicate that the dropout-associated signatures propagate azimuthally away from midnight. Observations by spacecraft beyond geosynchronous orbit in the dawn sector also suggest that they propagate slightly radially outward. This propagation signature is consistent with ground magnetometer data near the stations magnetically conjugate to the Van Allen Probes that show clear evidence for the eastward propagation of repeated disturbances (negative bays in H-component and often positive peaks in D-component, not shown). Ground magnetograms in the dusk sector show

263 complicated disturbances. Nonetheless, consecutive disturbances characterized mainly by
264 negative bays in H- and D-components are suggested to propagate westward (not shown).

4.2. All sky images

265 The overall propagation pattern of the dropout-associated features suggests event origin
266 in the magnetotail, followed by their earthward propagation to the inner magnetosphere,
267 and subsequent divergence to both dawn and dusk. We use all sky images, which provide
268 an effective 2-D display of the physical processes occurring in the magnetotail, to explore
269 this possibility. The THEMIS All-Sky Imager (ASI) [*Mende et al.*, 2008] data shown in
270 Figure 7A demonstrate that narrow north-south auroral forms, called auroral streamers
271 (marked by red arrows), appeared prior to each dropout. The streamers were primarily
272 seen at the stations, KUUI (58.10° north and 291.60° east in geographic latitude and
273 longitude), SNKQ (56.54° N and 280.77° E), and GILL (56.35° N and 295.34° E). They
274 mapped to the pre-midnight magnetotail during the event and propagated predominantly
275 towards lower latitudes, corresponding to earthward motion in the magnetotail. They
276 soon developed into, or coincided with, striated auroral structures that were extended in
277 the east-west direction.

278 The auroral keogram recorded at the subauroral Sodankylä station (SOD, 67.42° N and
279 26.39° E) in Finland close to the magnetic footprints of the Van Allen Probes according
280 to T96 model [*Tsyganenko*, 1995] shows that some disappearances of auroral intensifi-
281 cations correspond to the Van Allen Probes flux dropouts (indicated by vertical solid
282 magenta lines Figure 7B). Note that we plotted the image assuming that the height of
283 the emission is at 110 km. [*Sangalli et al.*, 2011]. The resulting forms of auroral inten-
284 sity surrounding the disappearance region suggest undulations of the poleward boundary

285 of auroral emission. Some of those features are omega bands, which are diffuse aurora
 286 distorted to an omega shape. The disappearances propagated to lower latitudes (blue ar-
 287 rows), again mapping earthward motion in the magnetotail, and eastward or azimuthally
 288 away from midnight (as consecutively observed at increasing magnetic longitudes). Time
 289 lags between (geographic) longitudes and durations of disappearance features seen in the
 290 keogram provide estimates for the azimuthal speed and size of the region: The azimuthal
 291 size of the disappearance region is $\sim 200\text{--}430$ km, and its eastward speed is $\sim 0.8\text{--}1.2$ km/s
 292 in the ionosphere. These numbers map to $\sim 0.5\text{--}1.1 R_E$ and $14\text{--}20$ km/s in the magneto-
 293 sphere according to the T96 model. The derived azimuthal velocity is consistent with the
 294 $\sim 2\text{--}5$ min lag for (averaged) event motion between RBSP-B and RBSP-A.

4.3. THEMIS observations of the magnetopause and upstream solar wind conditions

295 As indicated in Figure 1, the two ARTEMIS spacecraft (THEMIS-B and C), lying
 296 upstream from Earth and near the Sun-Earth line ($x \approx 57 R_E$) during the event, provide
 297 solar wind observations. Three THEMIS spacecraft (THEMIS-A, D, and E) monitored
 298 the response of the dayside magnetopause in the post-noon sector. Figure 8 shows (a)
 299 the IMF and (b) the solar wind (dynamic, thermal, magnetic, and total) pressures and
 300 density observed by THEMIS-C. Panels (c) and (g) depict the magnetic field, (d, h) the
 301 bulk plasma flow velocity, (e, i) the plasma temperature and density, and (f, j) the ion
 302 energy spectrogram measured by THEMIS-A (middle panels) and D (bottom panels).

303 During the event, THEMIS-C observed an IMF that pointed strongly southward with
 304 a y -component that changed from duskward ($+B_y$) to dawnward ($-B_y$). THEMIS-E
 305 and THEMIS-A, which were on an outbound trajectory behind THEMIS-D, spent most

306 of the interval from 0100 UT to 0630 UT in the magnetosheath, as indicated by the
 307 southward magnetic field, $-B_z$, significant flow velocities in the anti-sunward ($-V_x$) and
 308 duskward ($+V_y$) directions, low ($\lesssim 200$ eV) temperatures with high densities, and larger
 309 ion populations below ~ 1 keV. THEMIS-A and THEMIS-D did make multiple intermit-
 310 tent excursions into the magnetosphere and/or its magnetopause current layer, where
 311 ~ 10 keV magnetospheric ions leaking out from the magnetosphere coexist with magne-
 312 tosheath plasmas (Figure 8j), at times marked by red vertical dot-dashed lines. The
 313 magnetosphere can be characterized by $+B_z$, reduced flow velocities, higher temperatures
 314 with lower densities, and ion populations with energies above ~ 1 keV. The multiple mag-
 315 netopause or boundary-layer crossings indicate that the dayside magnetosphere repeatedly
 316 expanded outward and contracted. About 13–15 min before each of these dayside expan-
 317 sion episodes, THEMIS-C consistently observed reduced solar wind (dynamic) pressures,
 318 primarily resulting from depressed densities (blue shading in Figure 8). The ~ 13 – 15 -
 319 min interval corresponds well to the time required for solar-wind features transit from
 320 THEMIS-C to THEMIS-A/D with an average velocity of $V_x \approx -380$ km/s as observed by
 321 THEMIS-C (not shown), suggesting that the repeated dayside expansions were triggered
 322 by intermittent reductions in the solar wind dynamic pressure.

323 The number of times that the dayside magnetopause was abruptly disturbed (expanded)
 324 is similar to the number of flux dropouts observed by the Van Allen Probes (denoted by
 325 red shaded regions at the bottom of Figure 8). The first expansion occurred ~ 5 min prior
 326 to the first dropout at the Van Allen Probes. Later magnetopause expansions precede
 327 each of the following dropouts by ~ 20 – 30 min, except for the fifth dropout (marked
 328 by light red shading at the bottom of Figure 8) that follows ~ 5 min after the dayside

329 expansion. Furthermore, the longest dayside expansion beginning at ~ 0303 UT can be
330 linked to the longest duration dropout feature starting at ~ 0333 UT at the Van Allen
331 probes. In Section 5, we review previously proposed hypotheses about the dynamics
332 causing the flux dropouts and formulate a new one that can plausibly explain multi-
333 spacecraft measurements of dropout-associated signatures including our timing analysis
334 results.

5. Magnetospheric dynamics causing the flux dropouts

335 A number of researchers have addressed the multiple abrupt flux dropouts that are
336 observed by the Van Allen Probes deep ($L \approx 5$) within the magnetosphere. Some attribute
337 these dropouts to duskward then dawnward IMF and the strongly southward IMF during
338 the storm (Figure 8a). The IMF- B_y component might have caused a substantial tilt of the
339 magnetotail current sheet (or magnetic equatorial plane), placing the Van Allen Probes
340 repeatedly in the open field-line (lobe-like) region where rarefied plasmas of both thermal
341 and energetic populations are present [Cowley, 1981; Khurana *et al.*, 1996]. Because the
342 Earth's dipole lies relatively close on the noon-midnight meridional plane during the event,
343 the effects of the dipole tilt on the dawn-dusk tilt of the magnetotail current sheet are
344 insignificant.

345 However, the predicted IMF- B_y tilt effect and the magnetic field variations observed by
346 the Van Allen Probes during the dropout events are inconsistent: The first three dropouts
347 from ~ 0200 UT to 0340 UT occurred during a positive IMF- B_y (Figure 8), under which
348 the magnetotail plasma and current sheets should tilt counter-clockwise when seen from
349 the Sun, since dayside reconnection adds flux to the northern dawn and southern dusk
350 lobes under these conditions. The nearly equatorial Van Allen Probes should then lie

351 north of the equator and observe a positive B_y . However, as illustrated in Figure 2(b),
352 the Van Allen Probes observe a strongly negative B_y when they enter the flux dropout
353 regions. Furthermore, as seen in Figure 8(a), IMF- B_y changes sign from positive to
354 negative at ~ 0330 UT during the period of the event. The sense of tail plasma sheet tilt
355 should, accordingly, change from counter-clockwise to clockwise when the flux resulting
356 from dayside reconnection is deposited in the northern dusk and southern dawn lobes.
357 The equatorial Van Allen Probes should then lie south of the tilted equator and observe
358 a negative B_y . However, as seen in Figure 2(b), the probes observe a weaker negative
359 B_y during the fourth to sixth dropouts (after ~ 0345 UT) than they did during earlier
360 dropouts.

361 The extended period of strong IMF intensity might have caused unusually stretched
362 magnetotail configurations and/or north/south compressions of the magnetosphere, as
363 indicated by the stretched magnetic field lines ($\sqrt{B_x^2 + B_y^2} > |B_z|$) in the inner magne-
364 tosphere at the Van Allen Probes location (Figure 2a-c). From the negative B_y that the
365 probes observed, we know that the Van Allen Probes were located south of the magnetic
366 equator. The large IMF might distort magnetospheric magnetic fields and cause these
367 spacecraft to lie near the boundary between the plasma sheet and the southern lobe, oc-
368 casionally crossing the open-closed boundary according to the magnetospheric responses
369 to the solar wind driver. *Glocer et al.* [2013] and *MacDonald et al.* [2013] developed this
370 scenario and successfully reproduced the Van Allen Probes and LANL observations using
371 the global MHD numerical codes and field-line mapping technique. The different times
372 when the various spacecraft observe the series of flux decrease in the dawn and the dusk
373 sector would result from local structure in the open-closed boundary.

374 Another interpretation of the Van Allen Probes flux dropout is that a series of plasma
375 bubbles are created in the magnetotail and propagate earthward past the RBSP-B and A
376 spacecraft, consecutively [Lee *et al.*, 2013]. The IMF- B_y -associated tilting and/or global
377 compression/stretching of the magnetosphere should be more readily detected at the flanks
378 of the magnetosphere than near midnight, which is opposite to the Van Allen Probes and
379 LANL observations (Section 3.1 and 3.2). The bubble scenario, therefore, interprets each
380 event as a localized, transient phenomenon, requiring no clear one-to-one correspondence
381 of the dropout observations amongst widely-distributed spacecraft. However, we note that
382 plasma bubbles that are characterized by low entropy are expected to penetrate radially
383 inward via the interchange instability, which is not consistent with our multi-spacecraft
384 timing analyses of the mainly azimuthal, but also radially outward propagation of the
385 dropout signatures (see Figure 9A). More importantly, the rapid and intense magnetic
386 signatures during the dropouts cannot be explained by this hypothesis because a localized
387 bubble that carries a large negative B_y within it cannot penetrate into the dipolar inner
388 magnetosphere.

389 We, therefore, formulate a new hypothesis where the flux-depleted regions are inter-
390 preted as magnetic flux bundles or flux ropes (Figure 9). These events occurred during
391 the extended period of strong southward IMF, which caused magnetotail reconnection to
392 proceed from closed plasma sheet to open lobe magnetic fields, with time. The strong IMF
393 also leads the plasma sheet to thin enough that the tearing instability occurs at multiple
394 places along the tail current sheet, generating flux ropes that contain low-density lobe plas-
395 mas as a result of the extended lobe reconnection and a significant axial (y -directional)
396 magnetic field component associated with a guide field of reconnection. Supposing that

397 intermittent decreases in the solar wind dynamic pressure or other unknown driver inher-
398 ent in the solar wind lead the dayside magnetopause to expand outward, the flux added
399 to the northern/southern lobes and tail due to dayside reconnection will most largely
400 compress the magnetotail region tailward of the previously thinned location, causing the
401 site of magnetotail reconnection to move anti-sunward. Then, the outflow jets earthward
402 of the new (and more distant tail) reconnection site push the previously-formed flux ropes
403 earthward. When these ropes reach the region of strong pressure gradients in the in-
404 ner magnetosphere, they cannot penetrate further, and then start to wrap around the
405 boundary, possibly moving to the northern or southern hemisphere off the equator.

406 The flux-rope scenario explains a majority of the observational features: (1) The lack of
407 precise timing coincidence between the dawn and dusk observations can be explained by
408 the fact that the flux-rope motion drifting in the dawn and the dusk sector will depend on
409 the local environments. The bursty bulk flow events [*Angelopoulos et al.*, 1992] observed
410 more often and/or stronger in pre-midnight sector than post-midnight [*Angelopoulos et al.*,
411 1994; *Dubyagin et al.*, 2010] may also explain the GOES observations of dusk-side dropouts
412 that are 9 – 15 min earlier than the dawn-side Van Allen Probes observations. (2) The
413 time lags of ~ 20 – 30 min from the THEMIS to the Van Allen Probes observations can cor-
414 respond to the duration required for the dayside dynamics to lead the nightside responses.
415 (3) The particle flux enhancement bounding the flux rope (flux dropouts) might be caused
416 by intense magnetic field squeezing particles out of the flux rope into the surrounding re-
417 gion [*Shirataka et al.*, 2006] and/or compression of the flux ropes on either side of the
418 flux rope, thereby explaining the GOES observations of the flux-depleted regions sur-
419 rounded by short-range flux increases (Figure 4). (4) The equatorward auroral streamers

420 seen before each dropout event and the striated, horizontally elongated structures, which
 421 develop shortly after those streamers, also support this scenario, corresponding to the
 422 earthward propagation of flux ropes and their draping around the pressure gradients,
 423 respectively. (5) The draping and/or spreading of flux ropes in the azimuthal direction
 424 (θ) disturb background magnetic fields, generating field-aligned currents ($J_{\parallel(z)} \approx -\frac{1}{r} \frac{\partial B_r}{\partial \theta}$),
 425 which explain the magnetogram variations in the dawn and dusk sectors (the reversals
 426 in D-components); Such disturbances in the magnetic field coupled to the auroral region
 427 can generate undulations of the poleward boundary of auroral emission or omega bands
 428 (Section 4.2).

429 Figure 10A lists boundary normals during the inbound and outbound crossings of each
 430 dropout region by the Van Allen Probes, calculated via magnetic-field minimum variance
 431 analysis [*Paschmann et al.*, 1998]. These normal directions observed by RBSP-A (left)
 432 and RBSP-B (right) are visualized in 3D in Figure 10B. Most normals for entrances into
 433 the flux dropout region point in the z direction whereas most normals for exits point in
 434 the x direction. Figure 11A illustrates the trajectory of the Van Allen Probes with respect
 435 to a motional magnetic flux rope. Since the spacecraft were nearly stationary, it must
 436 be the flux rope that moves past them. This cartoon explains the small dip (increase in
 437 magnitude) in the B_x components and sharp increases in B_z components at the entrance
 438 and exit of each dropout, respectively, that were noted in Section 2.1 and Figure 2.

439 Figure 11B demonstrates that the magnetic field variations observed during a single flux-
 440 dropout structure can be relatively well fit to a force-free flux rope model, where $\mu_0 \mathbf{J} = \alpha \mathbf{B}$
 441 (so that $\mathbf{J} \times \mathbf{B} = 0$). For a constant α , Ampere's law becomes a Helmholtz equation whose
 442 solutions are Bessel functions [*Lundquist*, 1950]. The flux rope in a force-free configuration

443 has a cylindrical symmetry, represented by the axial (B_A), tangential (B_T), and radial
 444 (B_R) components of the magnetic field: $B_A = B_0 J_0(aR)$, $B_T = B_0 H J_1(aR)$, and $B_R = 0$,
 445 where R is the distance from the axis, $H = \pm 1$ determines the handedness of the magnetic
 446 field, and B_0 and a are constants determined by the fit. Figure 11B shows the axial (b) and
 447 tangential (c) components, and the angle (d) made by the axial component to the total
 448 magnetic strength (with 90° corresponding to the core of the flux rope) during the fourth
 449 dropout episode at $\sim 0417\text{--}0429$ UT (dot-dashed curves in Figure 11B). Overplotted are
 450 the model values shown in solid curves. H is found to be -1 . B_0 and a in our fit are -182.0
 451 nT and $7.9 R_E^{-1}$ with a standard deviation of 0.10 and 0.14. These numbers correspond to
 452 an estimated magnetic flux of $\sim 1.4 \times 10^6$ Wb within a flux rope with a diameter of ~ 0.61
 453 R_E (~ 3900 km), which is consistent with the size of the auroral-emission disappearance
 454 regions (or omega bands) in Section 4.2. Fitting for other flux-dropout structures yields
 455 standard deviations of fitted B_0 and a ranging ≤ 0.25 and ≤ 0.17 , respectively, indicating
 456 a reasonable consistency between the measurements and the model-predictions.

6. Conclusions

457 This paper presents multi-spacecraft observations of the storm-time inner and outer
 458 magnetosphere during a multiple flux-dropout event, initially identified by the Van Allen
 459 Probes that exhibited considerable abruptness and intermittency. The event can be fur-
 460 ther distinguished from the flux dropouts typically observed during the main phase of
 461 geomagnetic storms by the unusual magnetic field topology (strong B_y) simultaneously
 462 observed with the dropout occurrence. We combined various measurements from in-situ
 463 spacecraft and ground-based magnetosphere monitors to define and understand the global
 464 features associated with the dropouts. The GOES, LANL, and Geotail spacecraft simi-

465 larly detected sudden repeated loss of particle flux and/or corresponding magnetic-field
466 changes with a similar occurrence frequency to the Van Allen Probes measurements. How-
467 ever, observational discrepancies in occurrence times and flux variation patterns between
468 those spacecraft differing in locations demonstrate that local magnetic geometry and/or
469 plasma environments determine the encounter of the event whatever generation mecha-
470 nisms underlying the event are. We reviewed hypotheses for the cause of the flux dropouts,
471 including crossings of the open-closed boundary and plasma bubble scenarios. We also
472 formulated a new hypothesis, i.e., a magnetic flux rope scenario, after combining dayside
473 magnetopause observations and multiple inner/outer magnetosphere data, together with
474 ground-based measurements (all sky images, keogram, and magnetograms). This hypoth-
475 esis explains various features of the Van Allen Probes (and GEO) observations including
476 time lags between the satellites detecting dropouts, repeated magnetic variations (B_x dips
477 and B_z peaks) with inbound/outbound normals when the probes entering/exiting the flux
478 dropout region, the size of the flux ropes predicted by a model fit, and short-range flux
479 increases surrounding the flux-depleted regions.

480 The sequence of events suggests strongly that the magnetospheric process triggering or
481 facilitating the event may have originated in the tail current sheet, then caused dropout-
482 associated signatures to propagate earthward and azimuthally away from the midnight.
483 The present event occurred when the magnetosphere was unusually highly stretched or
484 compressed in the north-south direction retains plenty of room for further studies in the
485 aspect of magnetospheric responses to strong interplanetary drivers. The global spa-
486 tiotemporal context of the event we constructed using multi-spacecraft and ground-based
487 measurements helps understand such a unique case study.

488 **Acknowledgments.** This study was supported, in part, by NASA's Van Allen
489 Probes grant to the Goddard Space Flight Center with data from THEMIS, GOES,
490 LANL, Geotail missions, ground magnetometers, and all sky imagers. Geotail, Van
491 Allen Probes, and THEMIS datasets were provided by the Space Physics Data Fa-
492 cility at Goddard Space Flight Center through their Coordinated Data Analysis Web
493 (<http://cdaweb.gsfc.nasa.gov>) and THEMIS Web (<http://themis.ssl.berkeley.edu/>). We
494 acknowledge S. Claudepierre for providing data from the MagEIS instrument of the Van
495 Allen Probes Mission. H. Singer (howard.singer@noaa.gov), G. Reeves (reeves@lanl.gov),
496 N. Partamies (noora.partamies@fmi.fi), and Y. Nishimura (toshi@atmos.ucla.edu) pro-
497 vided GOES, LANL, auroral keogram, and high-resolution all sky image data, respec-
498 tively. KJH thanks E. A. MacDonald for useful discussions. A portion of this work was
499 supported by NSF Magnetospheric Physics grant No. AGS-1305374.

Table 1. Observation times for Van Allen Probes, GOES, LANL, and Geotail spacecraft detection of the onset tie (upper times in UT) and the peak flux depression time (lower times) of the series of flux reduction. Extended dropout timings, 0205–0301 UT, 0305–0338 UT, 0353–0422 UT, and 0433–0509 UT are shown for LANL 1991-080. Times of weak flux reductions are parenthesized. A thick vertical line separates the dawnside (left-hand side) and the duskside (right-hand side) observations.

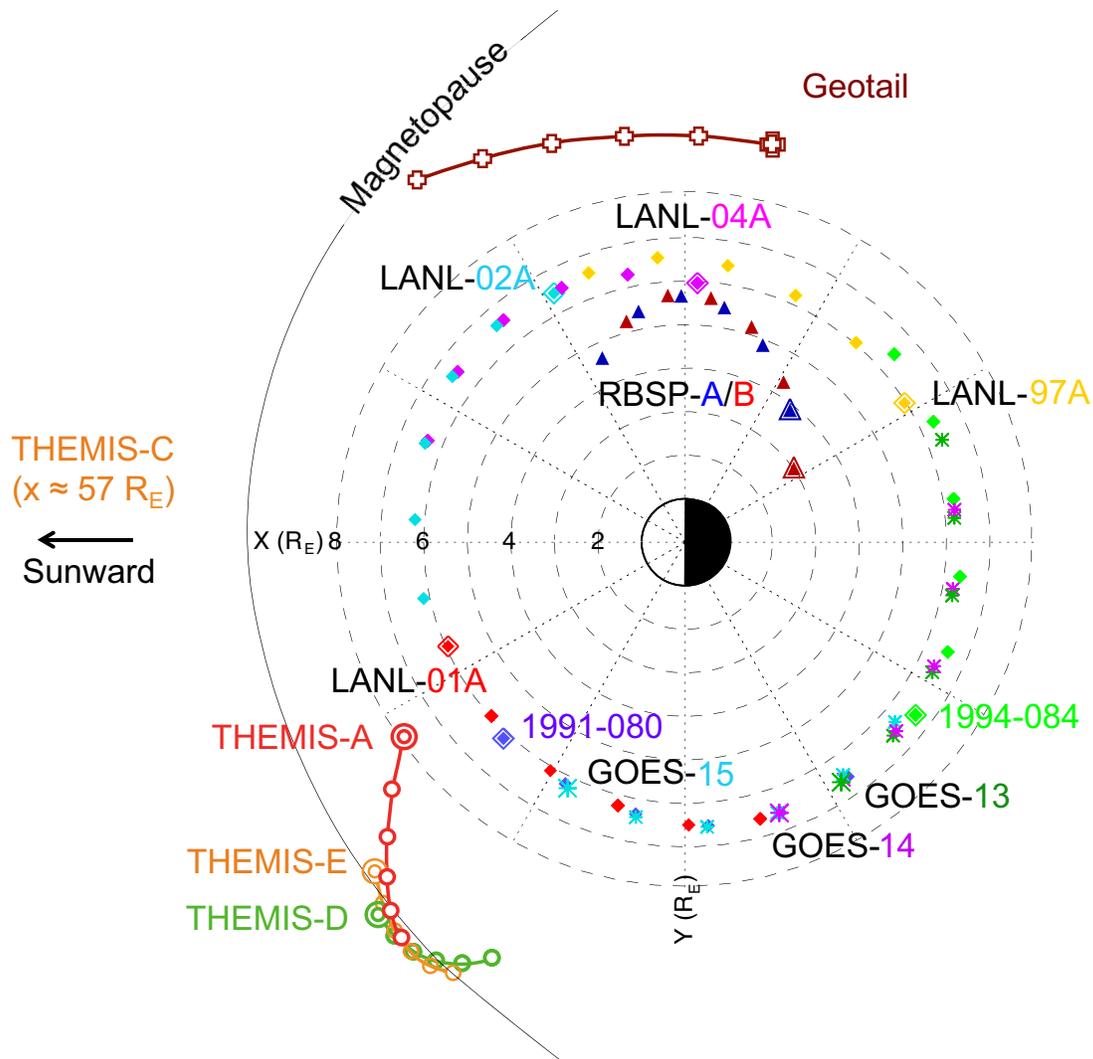

Figure 1. Location of Van Allen Probes (RBSP), GOES, LANL, Geotail, and THEMIS during 0100-0600 UT on 14 Nov, 2012 in the GSM XY plane. Each of six marks corresponds to the spacecraft location at 1–large mark to 6 UT by an hourly cadense. Two ARTEMIS probes in the upstream solar wind at $x \approx 57 R_E$ are indicated.

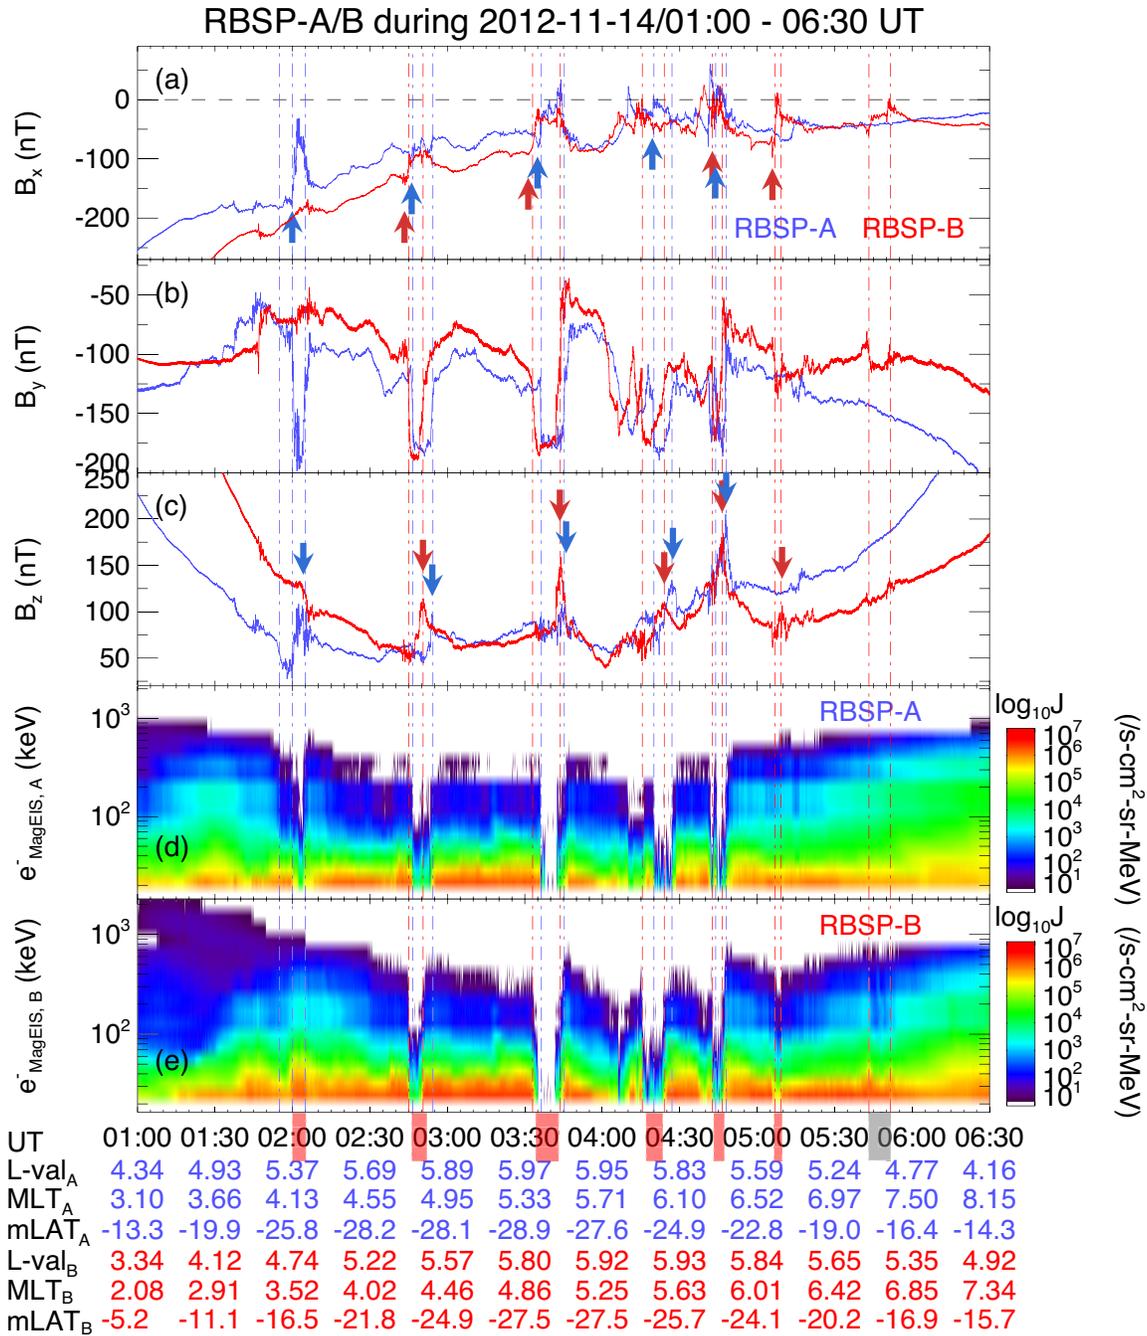

Figure 2. Van Allen Probes observations of a series of particle flux dropouts: (a-c) the (x, y, z) components of the magnetic field measured by RBSP-A (blue) and RBSP-B (red), (d, e) the electron flux spectrogram measured by the ECT/MagEIS instrument aboard RBSP-A (d) and RBSP-B (e). The magnetic latitudes shown in the bottom ephemeris are obtained from the T96 model [Tsyganenko, 1995].

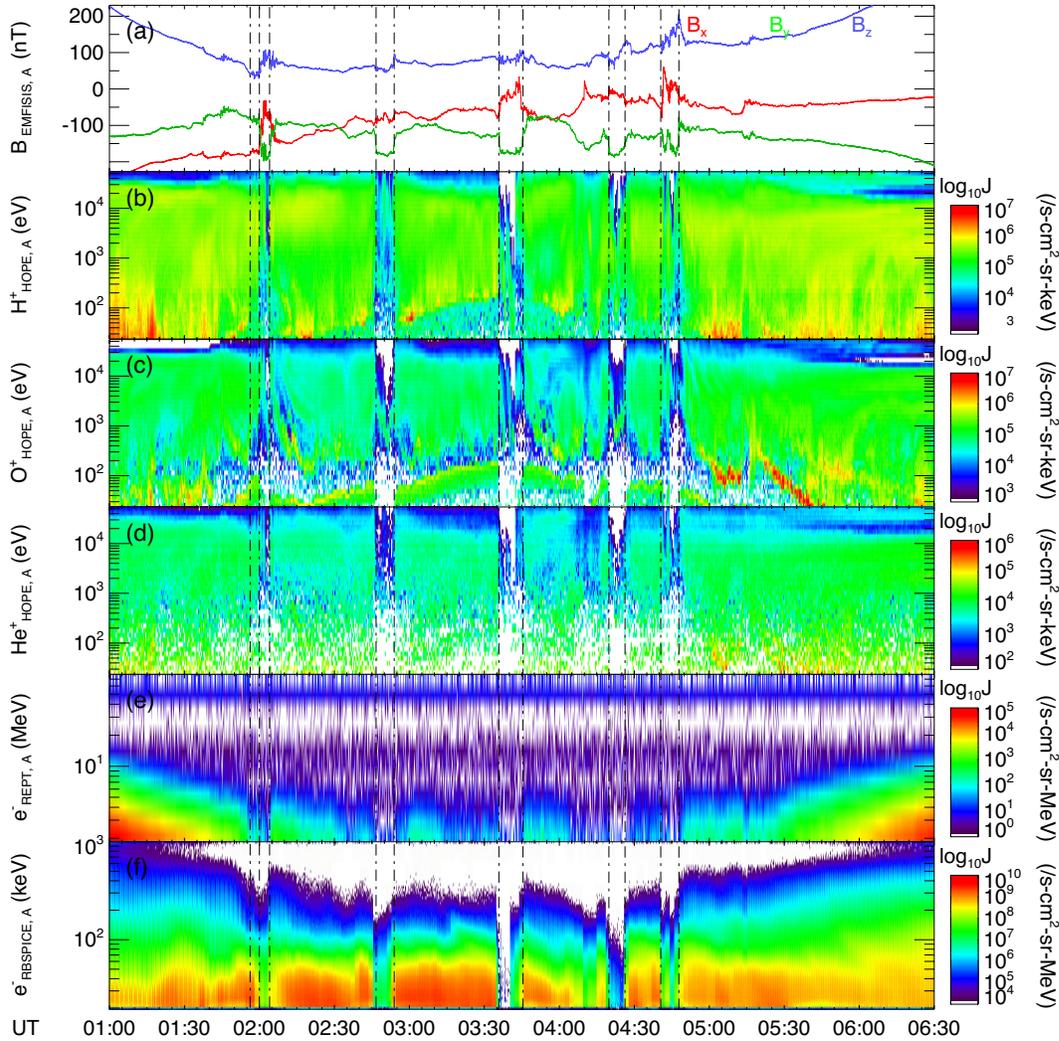

Figure 3. Van Allen Probes (RBSP)-A observations of the dropouts seen for multi-species ions and both thermal and energetic electrons measured by ECT/HOPE (b-d), ECT/REPT (e), and RBSPICE (d). The corresponding magnetic field changes are shown in the top panel (a). Note that the enhanced low-energy ions observed by HOPE are due to the effects of spacecraft potential, which is elevated during the storm time and accelerates these low-energy particles into the detector.

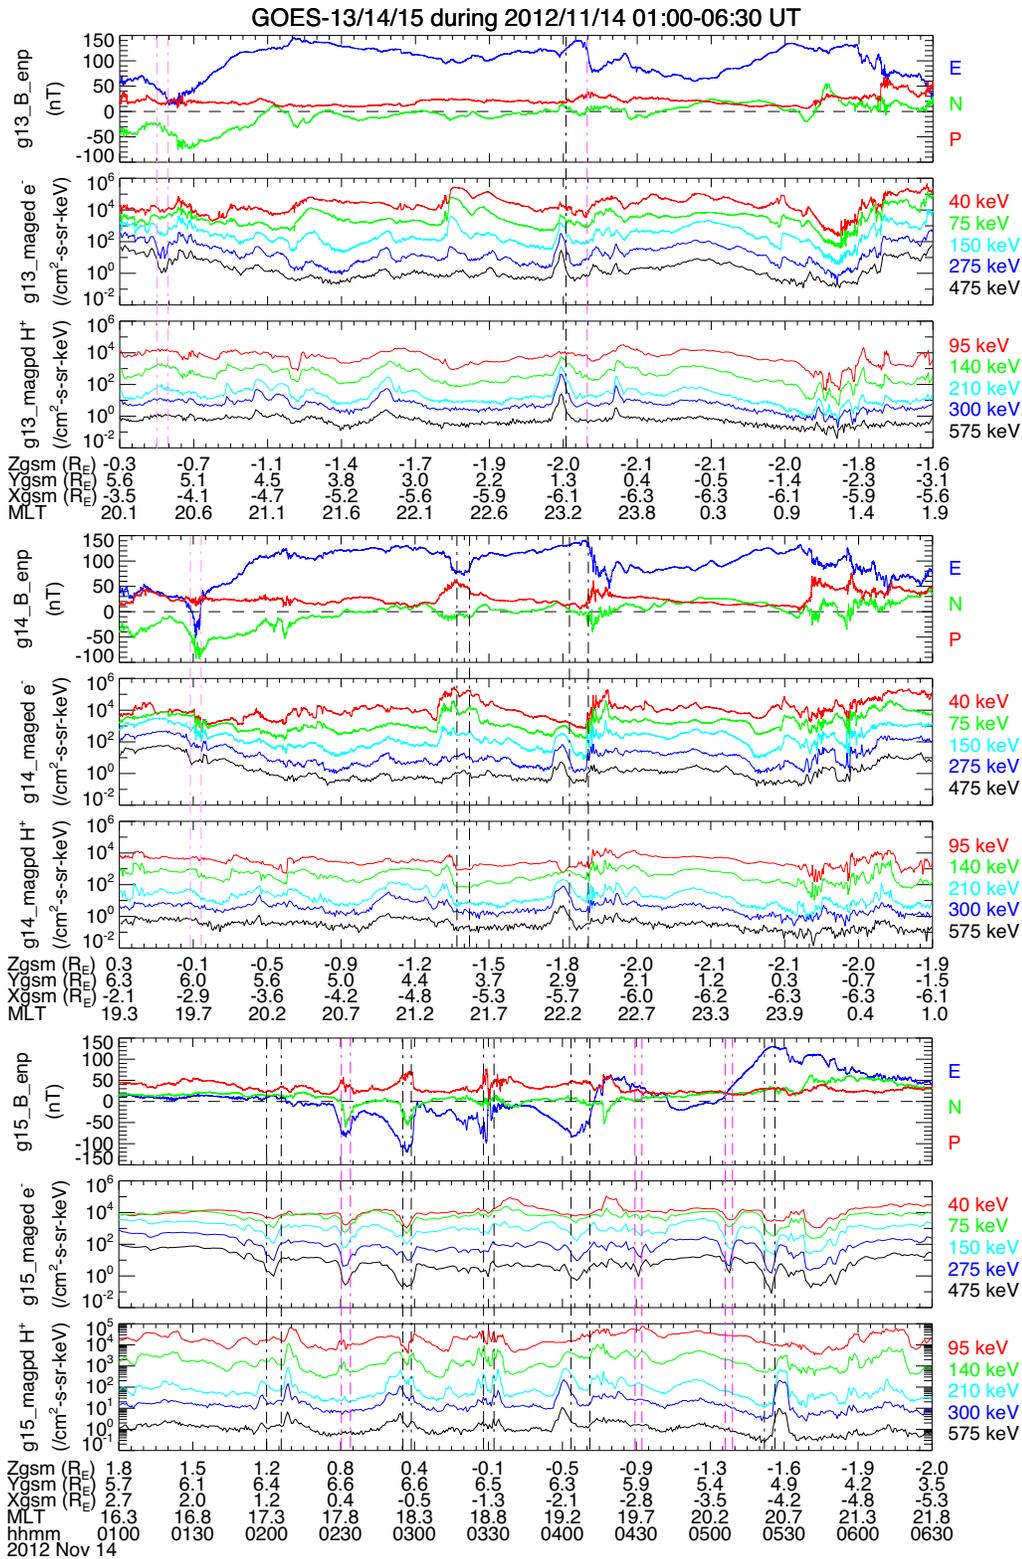

Figure 4. Three GOES spacecraft, GOES-13, 14, and 15 observations of the magnetic field with E (earthward), N (eastward) and P (northward) components and particle fluxes of electrons and protons during 0100–0630 UT.

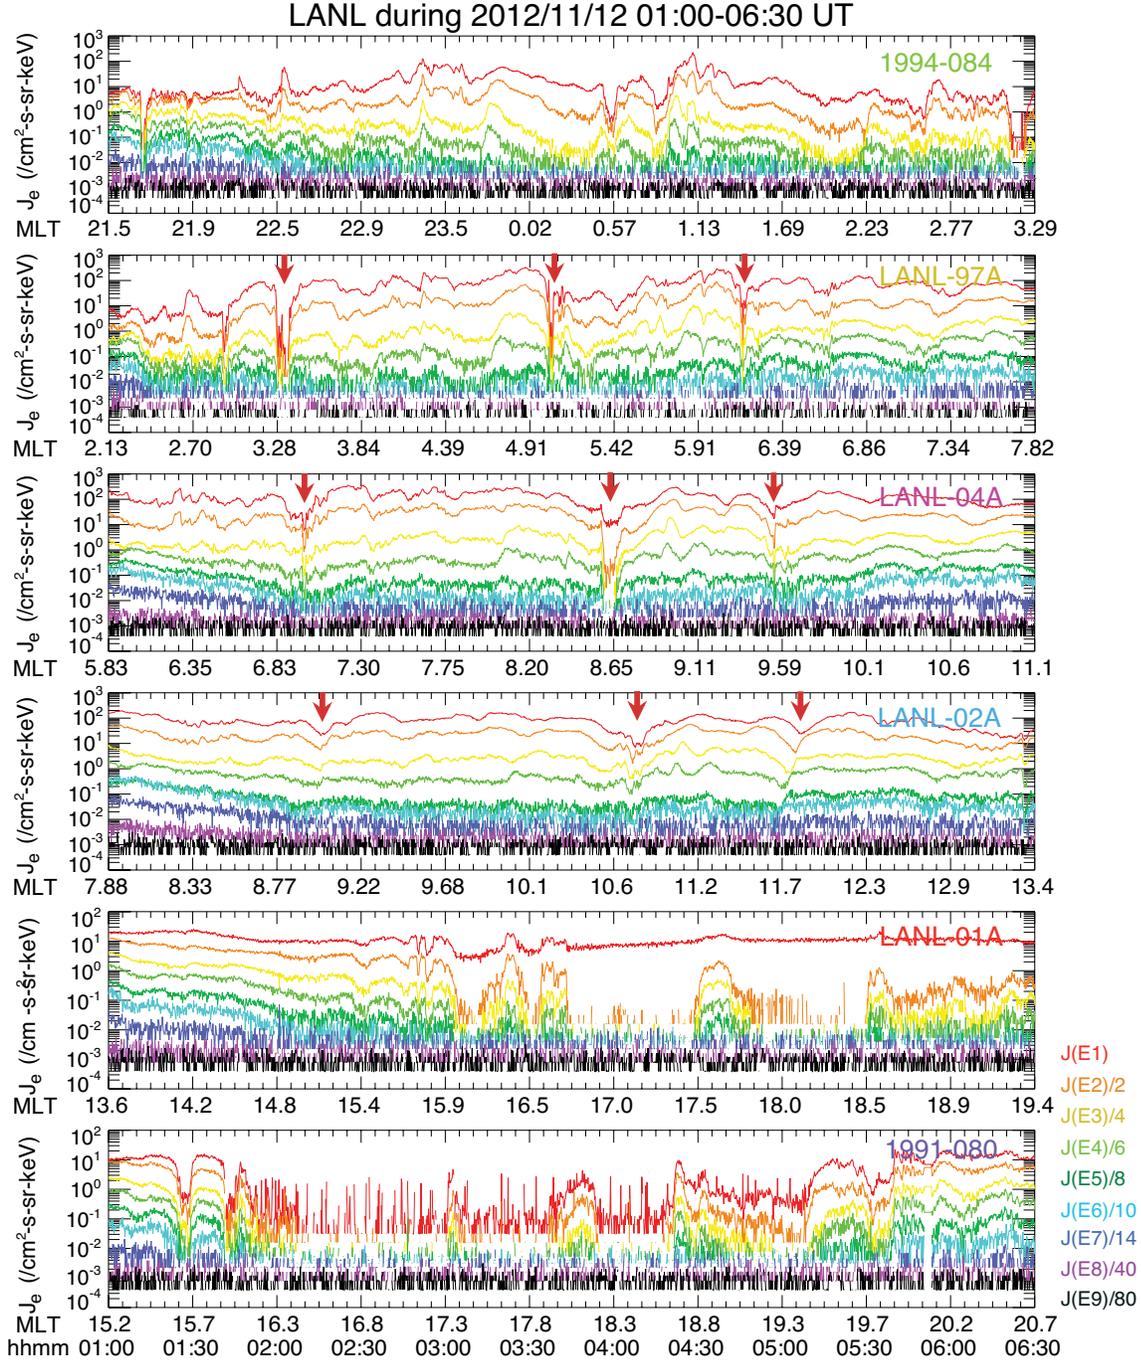

Figure 5. LANL spacecraft observations of dropouts in electron flux. Colored profiles represent electron flux in nine (E1 to E9) differential energy channels (E1: 50–75 keV, E2: 75–105 keV, E3: 105–150 keV, E4: 150–225 keV, E5: 225–315 keV, E6: 315–500 keV, E7: 500–750 keV, E8: 750–1100 keV, and E9: 1100–1500 keV). Weighting is applied for a better viewing of the flux variations.

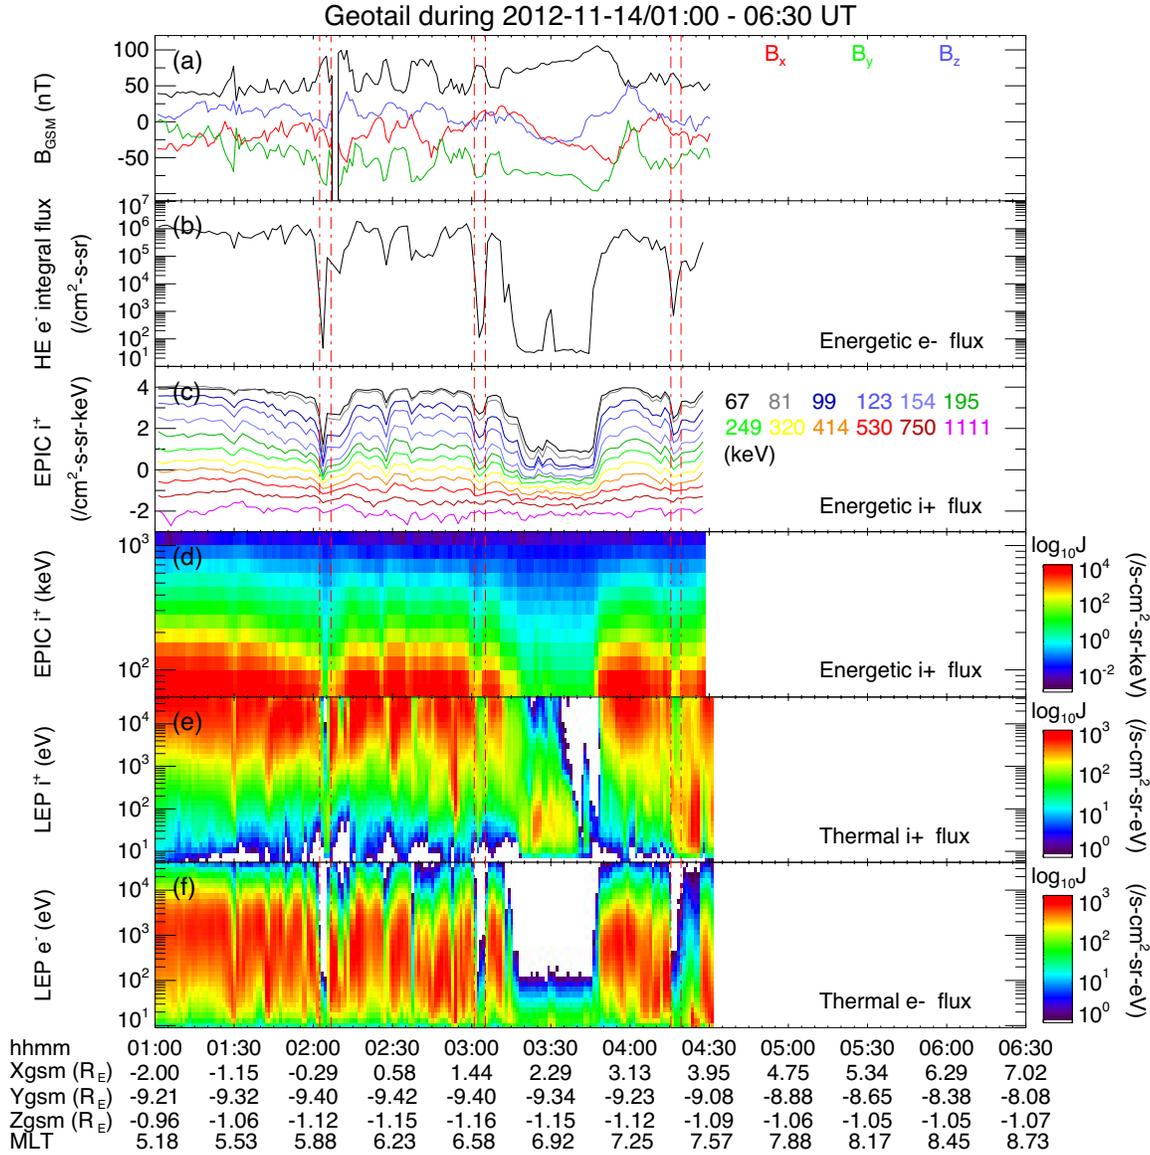

Figure 6. Geotail spacecraft observations: (a) magnetic field, (b) energetic electron flux, (c, d) energetic ion flux, (e, f) thermal ion and electron flux. Note a data gap between 0430 UT and 0630 UT.

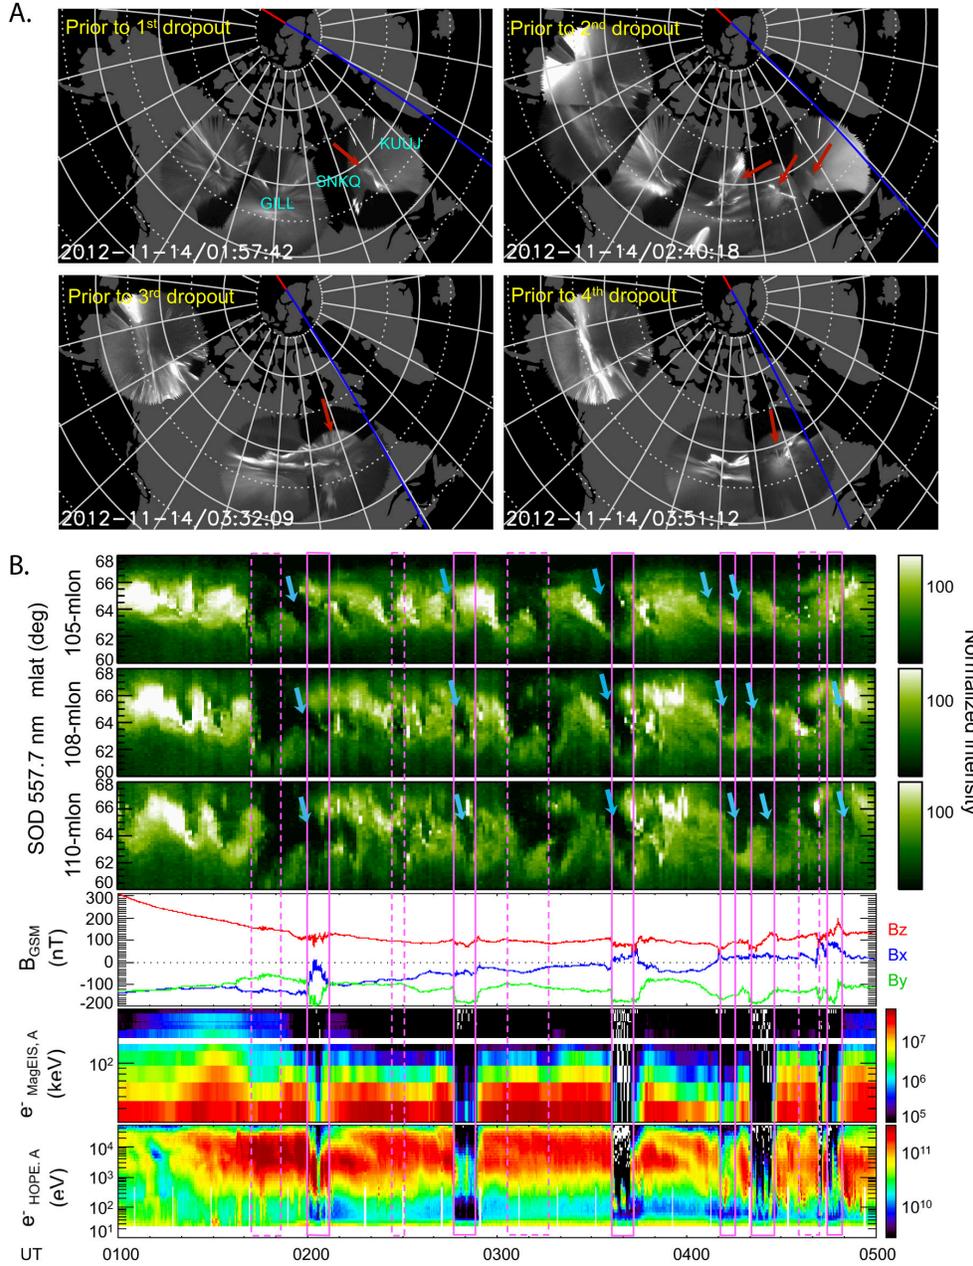

Figure 7. A. THEMIS All-Sky Imager (ASI) data showing narrow north-south auroral forms, called auroral streamers, prior to the first to the fourth dropout. Blue line denotes the midnight meridian. B. Auroral keogram at multiple magnetic longitudes recorded from the Sodankylä station (SOD) in Finland close to magnetic footprints of the Van Allen Probes. Disappearance of auroral intensifications that are possibly Omega bands are correlated with the Van Allen Probes observations of flux dropouts, indicated by vertical solid lines. Vertical dashed lines mark no clear correlations.

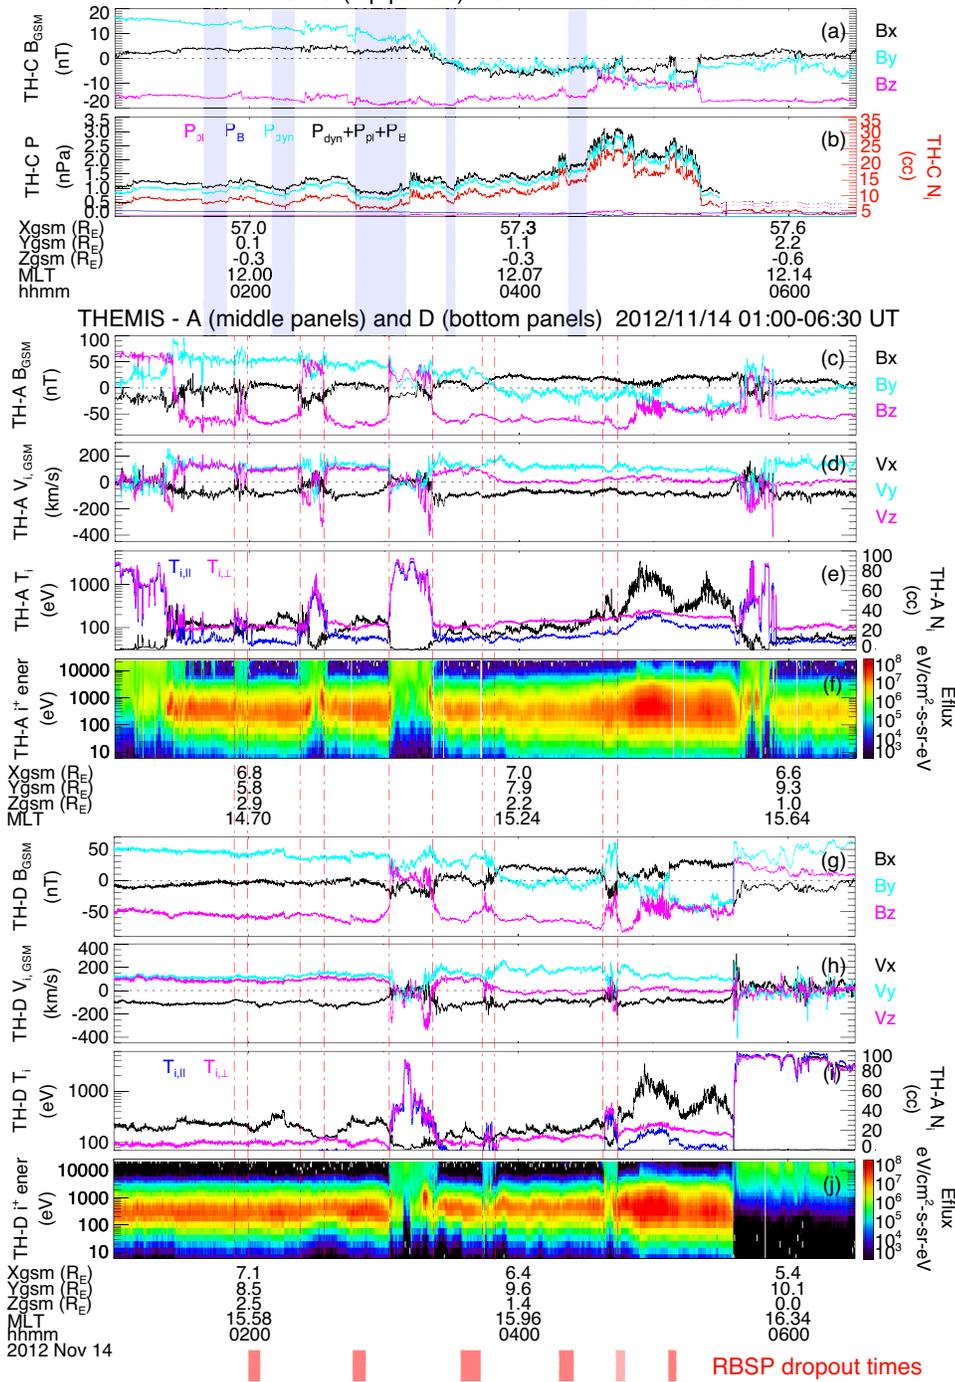

Figure 8. Observations by ARTEMIS (THEMIS-C) spacecraft, lying mostly on the Sun-Earth line ($x \approx 57 R_E$) and THEMIS-A and D passing the postnoon-side magnetopause during the event: (a) the IMF and (b) the solar wind pressure and density observed by THEMIS-C (top panels), (c, g) the magnetic field, (d, h) the flow velocity of bulk plasmas, (e, i) the plasma temperature and density, and (f, j) the ion energy spectrogram measured by THEMIS-A (middle panels) and D (bottom panels).

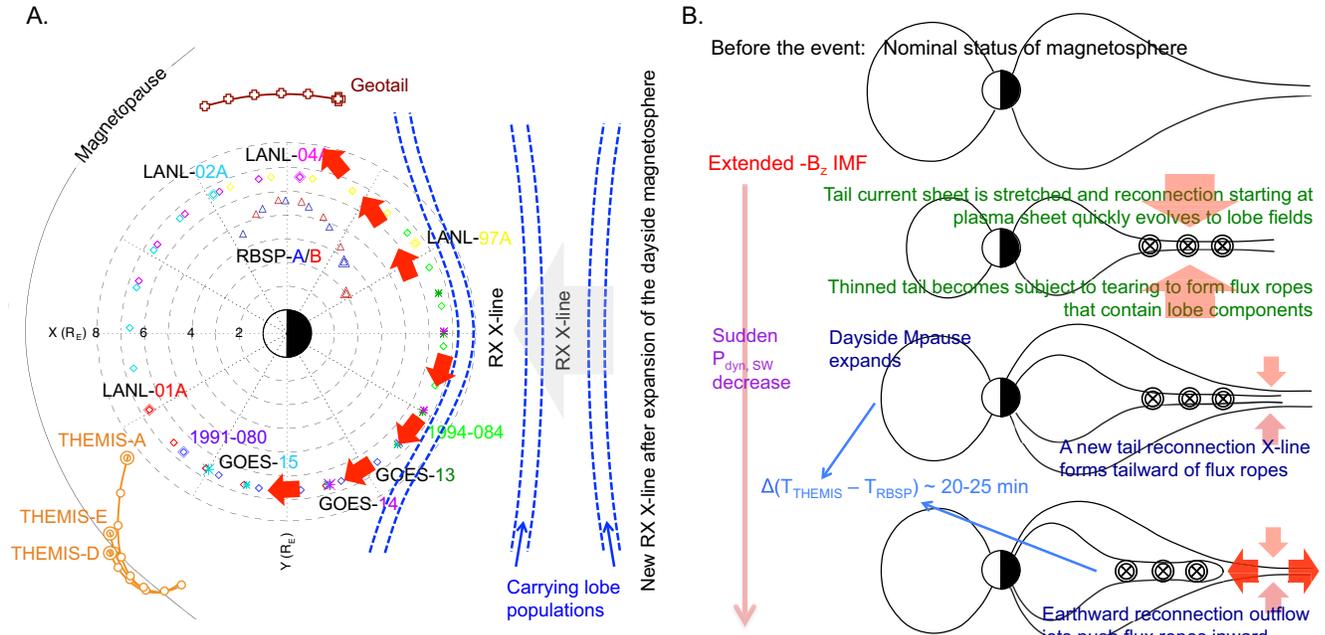

Figure 9. Illustrations of the flux-rope hypothesis where the flux-depleted regions are interpreted as magnetic flux bundles or flux ropes, shown in the equatorial (xy) plane (A) and meridional (xz) picture in sequence (B): During the extended strong southward IMF, the tail current sheet is highly stretched, compared to a nominal status (top cartoon, B), that reconnection starting at plasma sheet involves lobe fields with time. The thinned current sheet also becomes subject to tearing instability to form magnetic flux ropes that contain lobe components as a result of lobe reconnection. Under sudden intermittent period of the solar wind dynamic pressure decrease (or other unknown causes inherent in the solar wind), the dayside magnetopause expands and a new tail reconnection X-line forms tailward of the previously-formed flux ropes. Earthward reconnection jets push those flux ropes inward. They cannot penetrate all the way into the inner magnetosphere due to pressure boundary, where they start to wrap and move around the boundary (A).

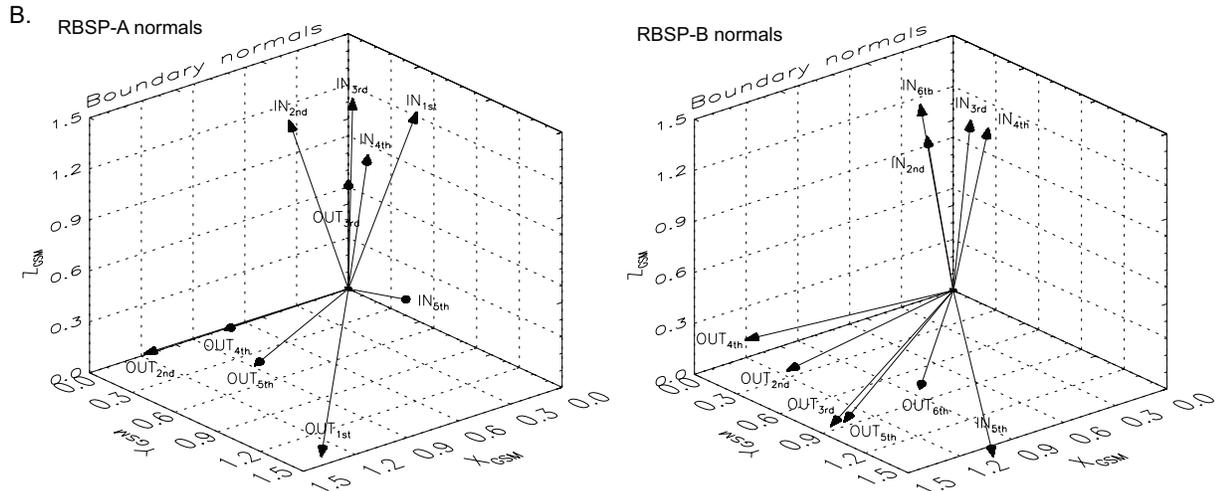

Figure 10. A. Boundary normals in GSM coordinates during the inbound and outbound crossings of each dropout region by the Van Allen Probes, calculated from the magnetic-field minimum variance analysis. The medium-to-minimum eigenvalue ratio in the minimum variance calculation is shown. The bootstrap error estimate for the minimum variance analysis [Kawano and Higuchi, 1995] shows a standard deviation of ≤ 0.047 . B. Illustrations of boundary normals observed at RBSP-A (left) and RBSP-B (right). For a majority of those boundaries, the inbound (outbound) normal when the Van Allen Probes entering (exiting) the flux dropout region mainly points along the z (x) direction.

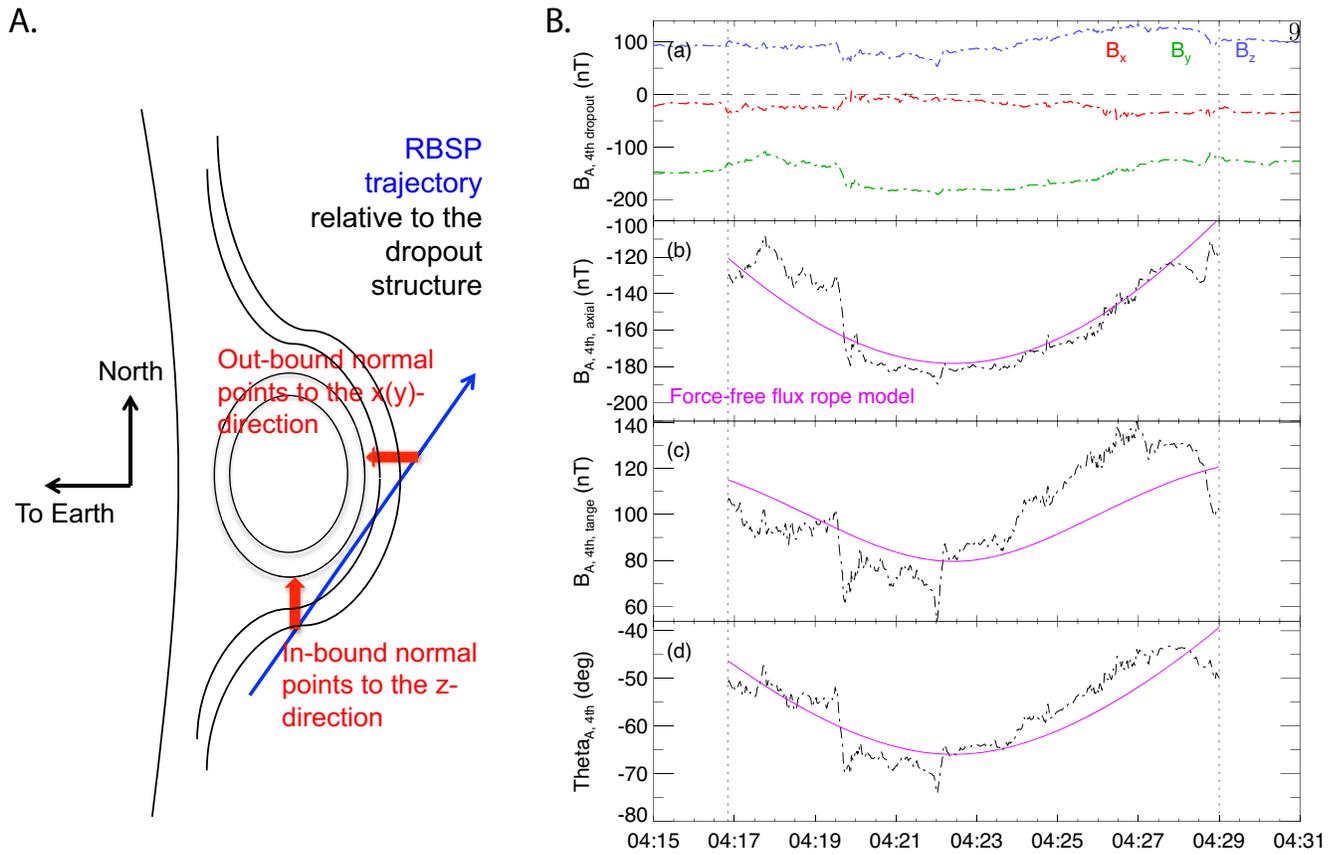

Figure 11. A. Illustration of the relative trajectory of the Van Allen Probes in the frame of the magnetic flux rope. This cartoon well explains a little dip (increase in magnitude) in B_x components and sharp increases in B_z components at the entrance and exit of each dropout, respectively, as shown in Figure 2(a and c). B. Fitting the observed magnetic field profiles (a) during a single period (the fourth flux dropout at $\sim 0417\text{--}0429$ UT) among the sequential flux-dropout structures to a force-free flux rope model, where $\mu_0 \mathbf{J} = \alpha \mathbf{B}$ (so that $\mathbf{J} \times \mathbf{B} = 0$). The flux rope in a force-free configuration has cylindrical symmetry, represented by the axial (B_A), tangential (B_T), and radial (B_R) components of the magnetic field. Axial (b) and tangential (c) components, and the angle (d) made by the axial component to the total magnetic strength (with 90° corresponding to the core of the flux rope) are shown in dot-dashed curves. Overplotted are the model values shown in solid curves.
