13

14 **Major Topic or Scientific Question:** EMIC waves are thought to be highly important  
15 drivers of energetic electron loss from the radiation belt, however, there are very few  
16 experimental examples of precipitation-causing EMIC-events with limited measurements of  
17 the waves or precipitation.

18 **New Scientific Knowledge:** Here we have, for the first time, simultaneous in-situ  
19 measurements of the properties of the EMIC wave, the plasma conditions, and the  
20 precipitation fluxes for a case study event, as well as 4 additional examples of EMIC driven  
21 precipitation.

22 **Broad Implications:** There is increasing evidence of the importance of EMIC waves to  
23 radiation belt dynamics. However, the lack of experimental quantification of the waves &

24 precipitation means they are only roughly estimated in radiation belt models. We provide  
25 measurements.

26

27 **Main point # 1:** EMIC waves thought to be highly important drivers of electron loss from  
28 the outer radiation belt.

29 **Main point # 2:** To date there are few experimental examples of precipitation-causing  
30 EMIC-events.

31 **Main point # 3:** Simultaneous insitu measurements of EMIC wave, plasma, & precipitation  
32 flux provided for first time.

33

34

35 **Abstract.** Electromagnetic Ion Cyclotron (EMIC) waves are thought to be important  
36 drivers of energetic electron losses from the outer radiation belt through precipitation into  
37 the atmosphere. While the theoretical possibility of pitch angle scattering-driven losses from  
38 these waves has been recognized for more than 4 decades, there have been limited  
39 experimental precipitation observations to support this concept. We have combined  
40 satellite-based observations of the characteristics of EMIC waves, with satellite and ground-  
41 based observations of the EMIC-induced electron precipitation. In a detailed case study,  
42 supplemented by an additional 4 examples, we are able to identify for the first time the  
43 location, size, and energy range of EMIC-induced electron precipitation inferred from  
44 coincident precipitation data and relate them to the EMIC wave frequency, wave power, and  
45 ion-band of the wave as measured in-situ by the Van Allen Probes. These observations will  
46 better constrain modeling into the importance of EMIC wave-particle interactions.

47

48 **1. Introduction**

49 It has long been recognized that wave-particle interactions with Electromagnetic Ion  
50 Cyclotron (EMIC) waves are an important driver for precipitation of relativistic electrons  
51 [e.g., *Thorne and Kennel*, 1971; *Summers and Thorne*, 2003; *Thorne*, 2010]. EMIC waves are  
52 observed in the Pc1-Pc2 frequency range (0.1-5 Hz). Unstable ion ring distributions of tens to  
53 hundreds of keV ring current ions cause the waves to be generated near the magnetic equator  
54 propagating as left-handed circularly polarized waves, hence the term "Ion Cyclotron".  
55 Recent experimental studies have shown EMIC wave growth can occur at all local times and  
56 can persist for hours and sometimes even days [*Paulson et al.*, 2014; *Saikin et al.*, 2015].  
57 Recent modeling studies have concluded that EMIC waves are very important sources of  
58 relativistic and ultra-relativistic electron losses from the outer radiation belt [e.g., *Drozdoz et al.*,  
59 *2015*; *Ni et al.*, 2015].

60 Despite the decades of recognition that EMIC waves could be significant drivers of electron  
61 precipitation, until recently there has been little experimental evidence of this. However,  
62 some progress is now being made. Some of the earliest confirmation comes from ground-  
63 based measurements showing evidence of relativistic electron precipitation from  
64 subionospheric VLF and riometer observations along with the start of simultaneous EMIC  
65 waves in ground-based magnetometers [*Rodger et al.*, 2008]. Following on from this the  
66 properties of probable EMIC-wave precipitation events detected using the expected signature  
67 for EMIC-wave driven losses seen in low-Earth orbit satellite data have been presented  
68 [*Carson et al.*, 2012]. One of these probable EMIC-wave precipitation events was  
69 investigated in a case study using multiple ground-based experiments [*Clilverd et al.*, 2015],  
70 and was confirmed to be intense and EMIC-wave driven, but with unexpectedly low-energy  
71 cutoffs <400 keV similar to those suggested by *Hendry et al.* [2014]. At highly relativistic  
72 electron energies, indirect evidence of the efficiency of EMIC waves to drive losses has been

73 provided by Canadian ground-based magnetometer data and  $>2.3$  MeV trapped relativistic  
74 electron from the Van Allen probes [*Usanova et al.*, 2014]. Thus, although there is increasing  
75 evidence of electron precipitation from EMIC waves, the detailed characteristics of the  
76 precipitation and associated waves remain uncertain.

77 However, there are many examples in the literature where EMIC waves are observed on the  
78 ground or in space for which there appear to be no electron precipitation occurring, even  
79 when the measurements are available [e.g., *Usanova et al.*, 2014; *Engebretson et al.*, 2015].  
80 There is also growing recent experimental evidence which suggest that EMIC-waves may  
81 precipitate electrons with energies as low as a few hundred keV [*Hendry et al.*, 2014;  
82 *Clilverd et al.*, 2015; *Blum et al.*, 2015] rather than the relativistic energies which are widely  
83 produced in theoretical modeling [e.g., *Meredith et al.*, 2003; *Chen et al.*, 2011; *Usanova et*  
84 *al.*, 2014]. There is some theoretical support for such comparatively low energy thresholds  
85 for EMIC-driven electron precipitation. The minimum resonant energy for a He-band EMIC  
86 wave inside the plasmasphere was shown to be as low as  $\sim 100$  keV for waves at  $\sim 1$  Hz  
87 [*Omura and Zhao*, Fig.2, 2013] and some quasi-linear theory has indicated minimum  
88 resonance energies of  $\sim 300$ -400 keV [*Summers and Thorne*, 2003; *Ukhorskiy et al.*, 2010].

89 In order to better constrain modeling and understand the importance of EMIC wave-particle  
90 interactions it is necessary to have in-situ observations of the wave and plasma characteristics  
91 for EMIC waves which are confirmed to be driving electron precipitation. In this paper we  
92 provide in-situ observations supported by ground-based precipitation measurements to fulfill  
93 this goal. We provide a detailed description of one event, identifying for the first time the  
94 location, size, and energy range of EMIC-induced electron precipitation caused by waves  
95 with in-situ measurements of EMIC wave frequency, wave power, and ion-band. We also  
96 provide the wave and plasma parameters for 4 other similar events.

## 97 **2. Experimental Datasets**

98 **2.1 Van Allen Probes Observations**

99 We make use of multiple experiments onboard the Van Allen Probes, in particular the  
100 magnetometer and ELF-VLF and LF observations from the Electric and Magnetic Field  
101 Instrument Suite and Integrated Science (EMFISIS) [Kletzing *et al.*, 2013], including the cold  
102 plasma densities measurements [Kurth *et al.*, 2015]. EMFISIS provides observations of the  
103 EMIC waves as well as the geomagnetic field intensities. Pitch-angle resolved electron fluxes  
104 are provided by the Magnetic Electron Ion Spectrometer (MagEIS) [Blake *et al.*, 2013] and  
105 the Relativistic Electron-Proton Telescope (REPT) [Baker *et al.*, 2013] instruments.

106

107 **2.2 Low Earth Orbit Precipitation Observations**

108 One source of precipitation observations comes from the Medium Energy Proton and  
109 Electron Detector (MEPED) instrument onboard the Polar-orbiting Operational  
110 Environmental Satellite (POES) [Evans and Greer, 2004]. This dataset is unusual in that it  
111 measures precipitation electron fluxes inside the bounce loss cone. The characteristics of the  
112 POES electron precipitation measurements have been comprehensively described in the  
113 literature [e.g., Rodger *et al.*, 2010a,b; Carson *et al.*, 2012].

114

115 **2.3 Ground-based Observations**

116 The other source of precipitation observations comes from narrow band subionospheric  
117 very low frequency (VLF) sites that are part of the Antarctic Arctic Radiation-belt dynamic  
118 deposition VLF Atmospheric Research Konsortia (AARDDVARK) network [Clilverd *et*  
119 *al.*, 2009; for further information see the description of the array at  
120 [www.physics.otago.ac.nz/space/AARDDVARK\\_homepage.htm](http://www.physics.otago.ac.nz/space/AARDDVARK_homepage.htm)]. Subionospheric VLF  
121 responds to electron precipitation which penetrates beneath the lower boundary of the  
122 ionosphere, that is electrons with minimum detectable electron precipitation energies of  
123 ~150 keV (day) and ~50 keV (night) [Rodger *et al.*, 2012].

124 **3. EMIC Event on 24 September 2013 - Wave Activity**

125 Figure 1 presents a set of spectrograms showing an EMIC event which started at 16:42 UT  
126 on 24 September 2013 observed by EMIFISIS onboard RBSP-A. The upper 3 spectrograms  
127 are the 3 components of the magnetic field in GSM coordinates. The lower panel of this  
128 figure shows the variation in the magnitude of the geomagnetic field, also observed by the  
129 EMIFISIS magnetometer. Shortly before the onset of the EMIC wave the geomagnetic field  
130 changes, with the magnitude of the total field altering by  $\sim 30$  nT in 4 minutes from  
131 16:40 UT. This change can also be seen in the He and O ion gyrofrequencies which are  
132 plotted as white lines in the spectrogram panels. It is likely that this magnetic field  
133 compression triggered the underlying instability that produced the wave, as has been  
134 previously observed across a wide range of MLT (see the discussion in *Engebretson et al.*  
135 [2015]).

136 This is a fairly strong and clear example of a He-band EMIC wave event. A summary of  
137 the wave and plasma properties determined from the EMFISIS observations of this event  
138 are given in Table 1, which shows that this event occurred in the afternoon sector and inside  
139 the plasmasphere, although it is likely to have been close to the plasmopause given the  
140 electron density value.

141 The upper panel of Figure 2 shows a spectrogram of the EMFISIS magnetic field ELF and  
142 VLF observations from RBSP-A across the same time period as shown in Figure 1. Here the  
143 spectrograms of the summed magnetic field components have been taken. The lower panel  
144 of this figure is the wave-normal angle for the observations shown in the upper panel.  
145 Typically, signals with wave normal angles  $<45^\circ$  are likely to be whistler mode waves,  
146 while those  $>75^\circ$  would be indicative of magnetosonic waves [*Gurnett and Bhattacharjee,*  
147 2005] that are restricted to the region of the geomagnetic equator. Figure 2 indicates that the  
148 ELF-VLF wave activity in the time period considered is quiet. Around this time there is a  
149  $\sim 100$ -200 Hz magnetosonic wave that is fading out, as well as a weak  $\sim 50$ -90 Hz

150 magnetosonic wave which starts around the time of the magnetospheric compression.  
151 Whistler mode wave activity is weak, particularly in the time period of the strong EMIC  
152 wave. It is well known that whistler mode waves can pitch angle scatter electrons and cause  
153 precipitation [e.g. *Thorne, 2010*], whereas magnetosonic waves are up to two orders of  
154 magnitude less effective at driving precipitation [*Shprits et al., 2013*]

#### 155 **4. Precipitation Observations**

##### 156 **4.1 AARDDVARK**

157 At 16:42 UT the northern hemisphere footprint of the RBSP-A spacecraft was located near  
158 Iceland. We have examined AARDDVARK data at this time, concentrating on Atlantic-  
159 longitude observations in the region of the RBSP-A observations. The upper two panels of  
160 Figure 3 show examples of the AARDDVARK observations made from St John's, Canada  
161 (STJ, red line) and Reykjavik, Iceland (REK, blue line). The amplitude and phase  
162 perturbations for two transmitters are plotted, with callsign NRK (red line in the Figure,  
163 located in Iceland) and NDK (blue line, located in North Dakota, USA). Figure 3 presents  
164 the change in amplitude in phase relative to undisturbed conditions, i.e., the change relative  
165 to the quiet day curve. There are clear amplitude perturbations starting at 16:42 UT (marked  
166 by the dashed vertical line). We observe consistent evidence of subionospheric  
167 perturbations beginning at the start time of the RBSP-observed EMIC wave seen in Figure  
168 1. As there is no significant whistler mode wave activity occurring at this time (as shown in  
169 Figure 2), the EMIC wave is the most likely candidate for driving the electron precipitation  
170 causing the observed AARDDVARK precipitation.

171 The lower panel of Figure 3 shows a geographic map of the AARDDVARK paths  
172 analyzed in this study. Note that there is both an AARDDVARK receiver and a VLF  
173 transmitter in Iceland, with the NRK transmitter symbol largely obscured. In this plot

174 AARDDVARK paths which were seen to respond to precipitation at the EMIC wave start  
175 time are shown in green, while the unresponsive paths are shown as dashed light blue lines.

176 The AARDDVARK observations are clearly consistent with precipitation occurring near  
177 Iceland around the  $L$ -shells of the RBSP-footprint. The size of the precipitation patch is  
178 sufficiently wide enough that transmitter receiver paths to the immediate east and west of  
179 Iceland are affected, but not so wide to affect those paths from Western European  
180 transmitters to Finland, or from NPM to the Antarctic station, Halley. The observed region  
181 of the EMIC-driven precipitation covers  $\sim 13$ -17 MLT.

182

#### 183 **4.2 POES Observations**

184 Near the start of the period during which the EMIC wave was observed by RBSP-A, there  
185 was a serendipitous conjunction with NOAA-15, one of the POES satellites that have been  
186 extensively used to investigate radiation belt precipitation. The orbital track of NOAA-15  
187 passed from south to north at the eastern edge of Iceland. At 16:41:55 UT the MEPED  
188 instrument onboard this satellite observed a burst of proton and electron precipitation with  
189 the signature expected from EMIC waves [*Sandanger et al.*, 2009], detected by an  
190 automatic algorithm [*Carson et al.*, 2012]. Such precipitation triggers have recently been  
191 shown to be associated with observed EMIC waves [Hendry, A. T., C. J. Rodger, M. A.  
192 Clilverd, M. J. Engebretson, M. R. Lessard, I. R. Mann, T. Raita, and D. K. Milling, First  
193 large scale survey of POES-detected EMIC wave driven energetic electron precipitation, *J.*  
194 *Geophys. Res.*, (in preparation), 2015.]. The location of this algorithm-trigger event is  
195 shown as the blue star in Figure 3, very close to the eastern end of the RBSP-A atmospheric  
196 footprint. As this observation was made at essentially the same location and time as the start  
197 of the RBSP-A EMIC wave observation, the precipitation includes both protons and a  
198 strong relativistic component as expected for effective EMIC-wave scattering, and RBSP-A

199 reports no significant ELF/VLF wave activity, we assume the POES precipitation event was  
200 produced by the observed EMIC wave.

201 The precipitation spike has been analyzed as described in section 3.2 of *Clilverd et al.*  
202 [2015]. By using the proton and electron precipitation measurements and a detailed  
203 understanding of the instrument response [*Yando et al.*, 2011], one can determine an energy  
204 spectrum, flux magnitude, and energy cutoff estimations for the observed precipitation. This  
205 precipitation event is best fit with a power-law, with spectral gradient values from -2.7 to -  
206 1.7, lower energy precipitation cutoffs of 140-230 keV, upper cutoff estimates of 1.6-  
207 8 MeV, and precipitation magnitudes of  $\sim 1.25 \times 10^4 \text{ cm}^{-2} \text{ sr}^{-1} \text{ s}^{-1}$ .

208

#### 209 **4.3 AARDDVARK Modeling**

210 The location of the POES trigger event and the RBSP-A footprints provide useful  
211 constraints on the likely longitudinal range of the precipitation affecting the paths from  
212 GQD and DHO to Iceland, i.e., the transmitters to the east of the Reykjavik receiver. We  
213 undertake modeling of the subionospheric perturbations predicted from precipitation  
214 defined by the POES energy and power-law gradient, using approaches previously  
215 described [e.g., *Rodger et al.*, 2012; *Clilverd et al.*, 2015].

216 We find that the modeling is sensitive to the initial conditions, for example comparatively  
217 small changes in the starting location of the energetic electron precipitation change along  
218 the path (i.e., changes of tens of km). This is likely due to the relatively short, all sea path  
219 from the transmitter to receiver, such that there is a high number of significant modes  
220 present in the Earth ionosphere waveguide, and also the small ionospheric region affected.  
221 Our modeling of the perturbations observed on the transmissions from DHO  
222 ( $\Delta\text{Amplitude} = +1.8 \text{ dB}$ ,  $\Delta\text{Phase} = -3^\circ$ ) and GQD ( $\Delta\text{Amplitude} = +0.6 \text{ dB}$ ,  $\Delta\text{Phase} = -3^\circ$ ), at the  
223 EMIC-wave onset time, indicates these changes are consistent with the effect caused by  
224 imposing the POES precipitation observations, i.e. flux magnitudes of  $\sim 1 \times 10^4 \text{ cm}^{-2} \text{ sr}^{-1} \text{ s}^{-1}$ .

225 The modeling reproduces the observations for power law gradients which have low energy  
226 cutoffs, i.e.  $\sim 200$  keV. It was not possible to successfully model the subionospheric VLF  
227 perturbations using low energy cutoffs of  $\sim 1$  MeV. Such cutoffs produce much larger  
228 amplitude and phase perturbations than observed. Therefore, the AARDDVARK  
229 observations confirm the POES satellite flux and energy cutoffs.

## 230 **5. Trapped Electron Flux Observations**

231 Figure 4 shows the RBSP-A MagEIS pitch angle resolved trapped fluxes with 1 MeV  
232 (upper panel) and 225 keV energies (lower panel). At the time of the magnetospheric  
233 compression and the start of the EMIC wave the fluxes change to a butterfly distribution,  
234 with a 50% decrease in the  $90^\circ$  pitch angles fluxes from 16:41-16:44 UT. A similar  
235 signature is seen in the MagEIS fluxes at energies  $>143$  keV, and in REPT fluxes  
236  $\leq 2.6$  MeV. The REPT fluxes  $>2.6$  MeV are at noise levels. There is no evidence of  
237 significantly different behavior between the 2.6 MeV fluxes and those at lower energies, in  
238 apparent contradiction to the conclusions of *Usanova et al.* [2014], although this could be  
239 obscured by the changes leading to the butterfly distribution.

240 Such butterfly distributions can be produced by magnetopause shadowing or by field line  
241 stretching and drift shell splitting [e.g., *Roederer et al.*, 1970; *Sibeck et al.*, 1987]. However,  
242 this does not explain the observations in our case, due to the small time dispersion between  
243 the energies. The source of the distribution should be only  $\sim 0.6$  MLT away to be consistent  
244 with the energy dispersion observed (i.e., located at  $\sim 16$  MLT). While we note that the  
245 butterfly distribution is unlikely to be caused by magnetopause shadowing, there has not  
246 been evidence suggesting such pitch angle distributions can be produced by EMIC waves.  
247 Nonetheless, the change to this distribution makes it essentially impossible to see evidence  
248 of the pitch angle scattering driving the observed precipitation.

## 249 **6. Additional Events**

250 In our examination of RBSP-A EMIC wave data and comparison with precipitation data  
251 we found 4 other events in which RBSP-A observed an EMIC wave, there was little  
252 evidence of confounding ELF/VLF whistler-mode wave activity, and AARDDVARK sites  
253 at Churchill (Canada), Fairbanks (Alaska), and Sodankylä (Finland) confirmed the presence  
254 of energetic electron precipitation. The RBSP-A in-situ measurements of EMIC wave and  
255 plasma parameters for these 4 additional events, along with those for 24 September 2013,  
256 are given in Table 1. All of these 5 events have butterfly distributions in the MagEIS  
257 trapped electron fluxes which begin near the wave start time.

258 In the current study we have chosen to concentrate on the analysis of the 24 September  
259 2013 event, due to the serendipitous conjunctions between RBSP-A, NOAA-15, and  
260 AARDDVARK network observations. None of the other events listed in Table 1 have such  
261 close conjunctions. We note that there are multiple POES-triggers on 27 August 2013, and  
262 that the events on this day may deserve more attention in a future study.

## 263 **7. Summary**

264 For the first time we have combined satellite-based observations of the characteristics of  
265 EMIC waves, with satellite and ground-based observations of the EMIC-induced electron  
266 precipitation. In a detailed case study, supplemented by an additional 4 examples, we are  
267 able to identify the location, size, energy range of EMIC-induced electron precipitation  
268 inferred from coincident POES/AARDDVARK data and relate them to the EMIC wave  
269 frequency, PSD wave power, and ion-band as measured by the Van Allen Probes.

270 We find that:

271 1. We find that the precipitation-causing EMIC waves typically occur over the MLT range  
272 16-00 UT, and at  $L \sim 5.4 \pm 0.4$ . The background plasmaspheric electron densities are  
273  $\sim 100$  el/cc, suggesting waves that are located close to the plasmapause. The frequency of

274 the EMIC waves are typically 0.3-0.5 Hz, and are mostly found within the helium band. The  
275 typical wave power spectral density is  $\sim 1 \text{ nT}^2/\text{Hz}$ , with peak powers  $\sim 10$  times higher.

276 2. The EMIC-induced electron precipitation was detected by the ground-based  
277 AARDDVARK network, with one coincident measurement made by one of the NOAA  
278 POES satellites. The region of electron precipitation was small in geomagnetic latitude, i.e.,  
279  $< 50 \text{ km}$  ( $\Delta L = 0.15$ ), but high in flux, i.e.,  $\sim 10^4 \text{ cm}^{-2}\text{sr}^{-1}\text{s}^{-1}$ , with a power law energy spectrum  
280 beginning at  $\sim 200 \text{ keV}$ . Radio wave propagation modeling of the AARDDVARK  
281 observations are supportive of the POES detection of a narrow latitudinal precipitation  
282 patch, as well as extended in longitude through several hours of MLT, and occurring at the  
283 time of the EMIC wave observed by RBSP.

284

285 **Acknowledgments.** The authors would like to thank Richard Yeo for hosting the  
286 AARDDVARK receiver in Reykjavik, the following institutional AARDDVARK hosts:  
287 Churchill Northern Studies Center USGS/Magnetic Observatories Fairbanks, and  
288 Sodankylä Geophysical Observatory. We would also like to acknowledge the researchers  
289 and engineers of NOAA's Space Environment Center for the provision of the data and the  
290 operation of the SEM-2 instrument carried onboard these spacecraft, the many teams  
291 involved in the Van Allen Probes, and the developers of the Autoplot interactive data tool.

Ion Band	He	H	He	He	He

425

426 **Table 1.** Properties at the times of the observed EMIC wave driven precipitation events.

427 The first event is that described in detail in this study. The parameters listed are as measured

428 by RBSP-A.  $f_{upper}$ ,  $f_{lower}$ : upper and lower EMIC wave frequency, PSD: EMIC wave power

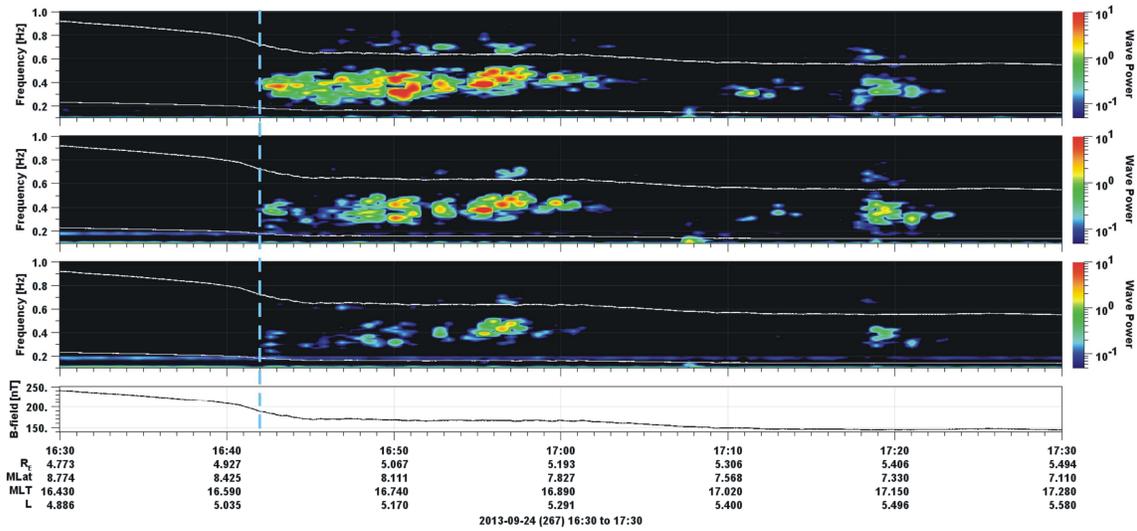

429 spectral density,  $N_e$ : cold electron density,  $f_{pe}$ : electron plasma frequency,  $f_{ce}$ : electron gyro-

430 frequency.

431

432

433

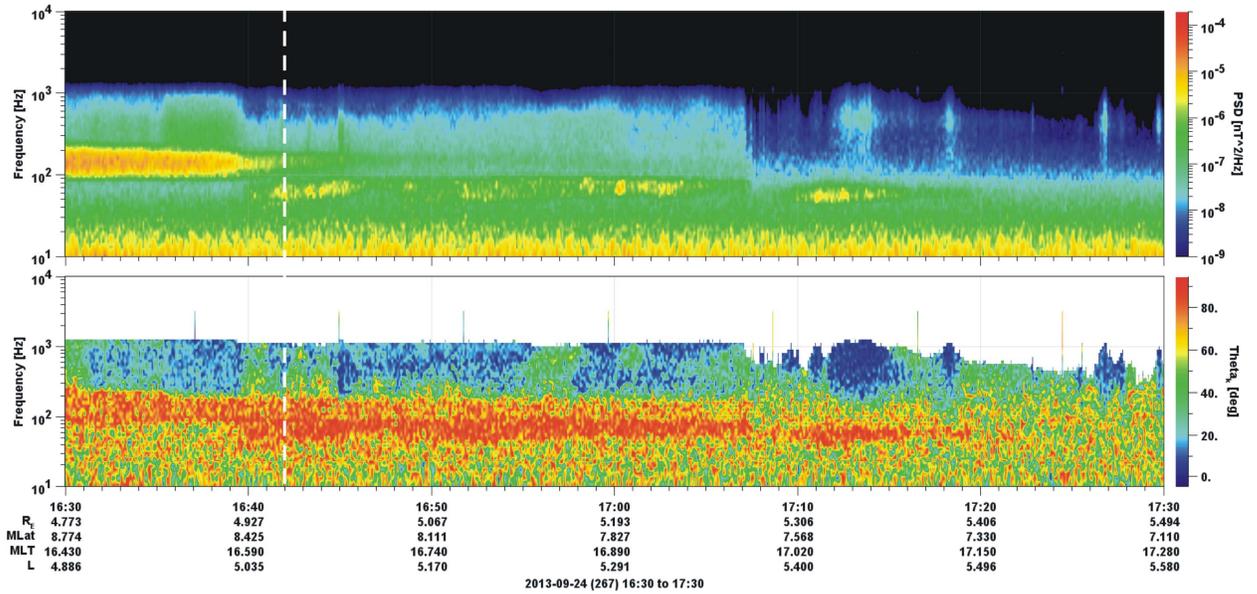

434

435 **Figure 1.** The three upper panels show spectrograms of the 3 components of the magnetic  
 436 field in GSM coordinates from the EMFISIS experiment onboard RBSP-A on 24 September  
 437 2013. Wave power has units of  $\text{nT}^2/\text{Hz}$ . The white lines show the local ion gyrofrequencies  
 438 for He (upper) and oxygen (lower) ions. The lowest panel presents the absolute value of the  
 439 DC magnetic field reported by the same instrument. A blue dashed line marks the start of  
 440 the EMIC-wave at 16:42 UT.

441

442

443

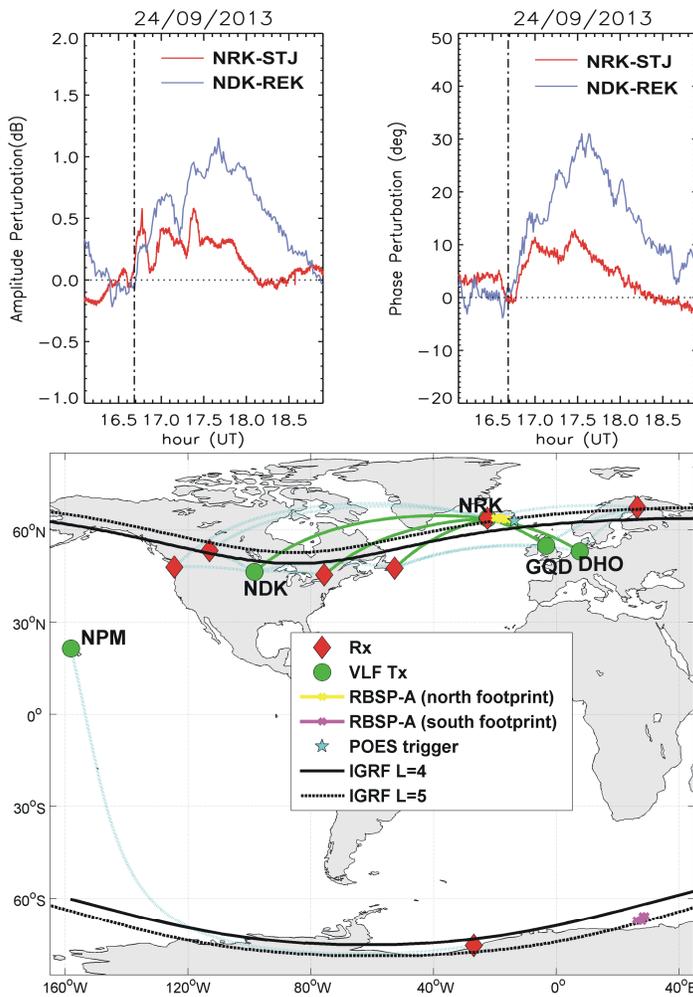

444

445 **Figure 2.** EMFISIS ELF/VLF magnetic field observations for the same time period shown  
 446 in Figure 1. The upper panel is the spectrogram of the summed magnetic field components  
 447 with units of  $\text{nT}^2/\text{Hz}$ . The lower panel shows the wave-normal angle with units of degrees,  
 448 determined from the upper panel waveforms.

449

450

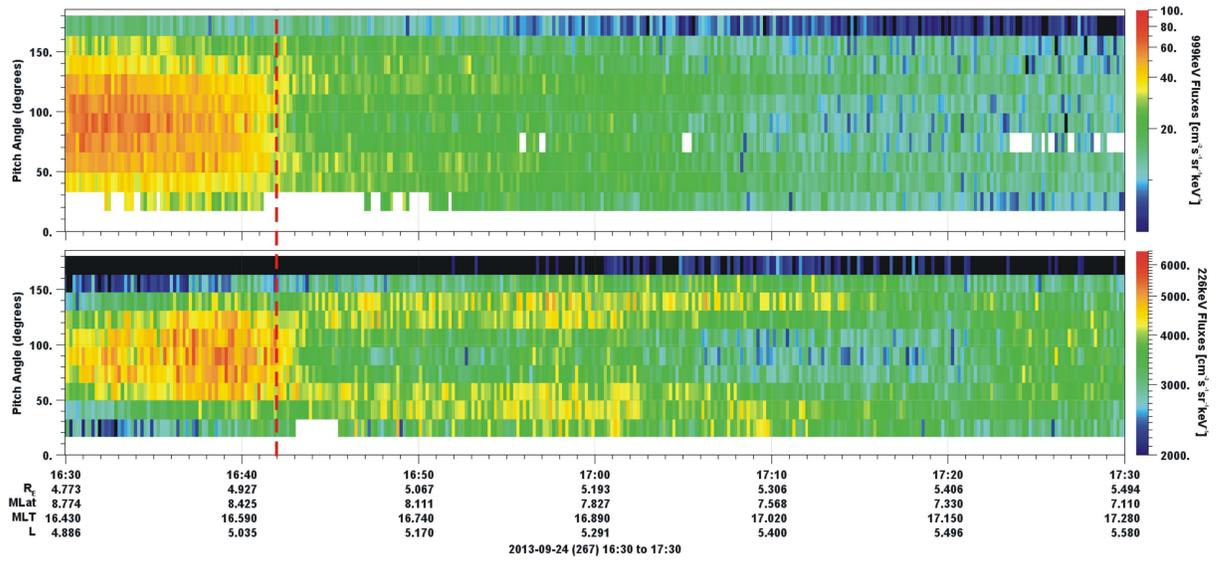

451

452 **Figure 3.** Summary of AARDDVARK observations at the event time. The upper panels  
 453 shows amplitude and phase perturbations observed on the path NRK-St John's (Canada)  
 454 (STJ, red) and NDK-Reykjavík (REK, blue). The black dashed line marks 16:42 UT. The  
 455 lower panel is a map of the AARDDVARK paths analyzed in this study. RBSP-A northern  
 456 (yellow) and southern (magenta) footprints are shown, as is the POES trigger sub-satellite  
 457 point (blue star), AARDDVARK receivers (red diamonds), and VLF transmitters (green  
 458 circles). In this plot AARDDVARK paths which were seen to respond to precipitation at the  
 459 EMIC wave start time are shown in green, while the unresponsive paths are shown as  
 460 dashed light blue lines.

461

462

463

464 **Figure 4.** Butterfly pitch angle distributions seen in the MagEIS 1 MeV flux distributions

465 (upper panel) and the 225 keV distributions (lower panel). The dashed red line marks the

466 start of the EMIC wave seen in Figure 1.

467
