Abstract

The study of high performance composites such as plastic-bonded explosives under extreme conditions often requires innovative experimental techniques. Here, static phase contrast imaging (PCI) of simulated explosive materials has been performed at high speed in an effort to determine feasibility of imaging material response to dynamic, high-strain rate events ($10^2 - 10^7$ s\textsuperscript{-1}). The microstructure of pristine materials, idealized composites and simulated explosive composites has been characterized with synchrotron PCI at the Advanced Photon Source. High spatial resolution (2μm) of the microstructure was achieved even with 5 μs exposures, and features such as interfaces, cracks, voids, and bubbles were clearly observed. The likelihood of obtaining sufficient phase information at even faster exposures (e.g. 0.2 μs) is shown to be high.

Keywords: A. Discontinuous reinforcement; B. Interface/interphase; B. Microstructures; D. Radiography
1. Introduction

Understanding and predicting detonation, failure and general deformation mechanisms in plastic-bonded explosive (PBX) composites is an important goal for the explosives community. PBX materials consist of micron-sized explosive crystals embedded in a polymer matrix. Typical formulation involves suspending the crystals in water and mixing the suspension with a polymer solution. The water crashes the dissolved polymer out of solution to create crystal-polymer agglomerate particles known as molding prills. The prills are then pressed to shape or compression molded into cylinders or pellets. The composites are highly loaded, usually greater than 85% crystals by weight, and both particle size and particle size distribution are known to affect the mechanical properties and detonation behavior [1-3]. The microstructure of PBX 9501, composed of 95% cyclotetramethylene-tetranitramine (HMX) crystals and 5% plasticized Estane 5703 by weight, is shown in Figure 1.
Figure 1. Microstructure of PBX 9501, showing a wide distribution of particle sizes and variability in crystal integrity: “A” is relatively defect free, while “B” contains inclusions. From Rae et al., used with permission [3].

The microstructure of the PBX, and in particular the crystal-binder interface, plays an important role in mechanical deformation events, including failure. Defects within crystals, at the crystal-binder interface, in the partially dissolved crystal-binder region (“dirty binder”), or within the binder itself may all contribute to formation of local inhomogeneities (“hot spots”) which initiate deflagration or detonation [4, 5]. Crack propagation between the crystals and the binder has been observed in many systems and is usually the failure mechanism of PBX materials under mechanical strain [6-8]. PBXs are difficult to study at the micro-scale or nano-scale with conventional techniques due to the complexity of the microstructure, the brittle nature of the molecular crystals, the compositional (low-Z) similarities between the crystals and the binder, and ease of thermal degradation or melting under an electron beam. The use of unique, innovative methods is often necessary to gather structural information for these materials.

X-ray study of composites is gaining in popularity as source and detector technology improves. Three dimensional applications such as tomography have been used recently to identify glass fiber orientation and distribution in sheet molding compounds [9] and reinforced polyamides [10] as well as microsphere and epoxy fracture in syntactic foams [11]. These tomography studies used phase contrast imaging (PCI) which allows greater resolution and contrast than traditional absorption radiography. For an excellent overview of the theoretical aspects of PCI, refer to the review by Wu and Liu [12]. While X-ray tube sources have been successfully used
for PCI in structural materials [13], synchrotron sources provide orders of magnitude higher brightness and coherence, allowing for higher resolution and shorter exposure times [14]. The exposure time advantage is particularly useful for samples which suffer localized heat degradation from beam exposure or must be studied on short time scales for other reasons.

Experiments using PCI present exciting possibilities for observing high strain rate deformation (e.g., shock waves) at the microstructural scale in PBX materials. A previous study at the Advanced Photon Source (APS) at Argonne National Laboratory achieved 10 μm spatial resolution of a tungsten – silicon reaction using ultrafast “white” radiation x-ray pulses and microsecond exposure times [15]. Our main objective in the current work was to assess the feasibility of performing high-speed PCI measurements on low-Z materials to study microstructure and defects using the synchrotron X-ray beam at APS and available X-ray detectors. These initial measurements will guide future dynamic loading experiments which will use high-speed PCI to investigate microstructural effects on the dynamic response of PBXs or similar composites. In contrast to quasi-static loading, dynamic loading experiments can readily examine a material’s response over a wide range of strain rates (10² s⁻¹ to 10⁷ s⁻¹) and timescales (ns to ms) making it possible to directly examine mechanical deformation in real-time.

Although such dynamic experiments are of great interest to the high-pressure community they pose significant technical challenges related to the use of x-ray detectors and x-ray sources mostly because of the short duration of the dynamic state, which significantly limits the number of photons available for detection. Synchronization of the dynamic event with the incoming photon bunch(s) and the detector is also required. These difficulties coupled with the high costs
of dynamic experiments warrant independent feasibility studies as presented here. Key targets of our study included determination of whether we could observe the microstructure at sufficient spatial and temporal resolution to study dynamic response and whether we needed to introduce a doping agent to achieve contrast between crystals and polymers. In addition, observation of cracks, voids, bubbles, or other defects would be particularly interesting. As a side benefit of our PCI feasibility study, we wanted to show that the technique could be useful for other types of low-Z composites, such as pharmaceutical tablets or polymer-matrix composites (PMCs).

2. Sample Preparation

In order to demonstrate the usefulness of PCI to studying specific microstructural features, simulated PBX samples with engineered microstructures were fabricated with a variety of processes. Sucrose (J.T. Baker, Phillipsburg, NJ) and acetaminophen (Acros, Morris Plains, NJ) were grown as single crystals from water or ethanol solutions, following the method of Ramos et al. for the sucrose [16] and the method of Finnie et al. for the acetaminophen [17]. The acetaminophen tends to crystallize from solution by spiral growth, usually resulting in highly defective surfaces [18], while sucrose surfaces can generally be grown with smooth surfaces. Sucrose and acetaminophen were chosen as simulants for the explosive HMX because they have similar crystal structure (monoclinic), solubility in certain solvents, and mechanical properties. Some single crystals were embedded in Angstrom Bond epoxy (Fiber Optic Center, Inc., New Bedford, MA) or the poly(ester urethane) Estane 5703 (B.F. Goodrich, Jacksonville, FL), while others were bonded together with water or epoxy to study crystal-crystal interfaces. Estane was chosen because it used in some explosive formulations and has been well-characterized.
previously [19]. Certain single crystals were intentionally damaged by creating a 250 μm trench in one surface with a wire saw.

Sucrose powder was also formulated into a plastic-bonded simulant (PBS) pellet using an identical procedure to that for PBX 9501, including using an identical plasticized Estane binder at 5 wt% [6]. The effect of doping was studied by using Bi₂O₃ nanoparticles (90-210 nm in diameter; MTI, Richmond, CA) to enhance contrast in some polymer-embedded samples. PBS pellets were produced with a range of thicknesses and in some cases the PBS molding prills were doped prior to pressing. Additionally, binder cracking was simulated by intentionally cracking a polymethylmethacrylate (PMMA) slab. General sample size along the probing direction was between 0.3 and 3.5 mm. A list of all studied samples is given in Table 1.

3. X-ray Characterization Experiments

PCI is much more effective for imaging than traditional radiography especially for low-Z materials. The complex index of refraction of a material for x-rays is $n = 1 - \delta i \beta$, where $\beta$ accounts for absorption, and $\delta$ contains phase information [12]. Traditional x-ray radiography relies on the spatial variation of $\beta$ to produce the intensity variation in the image, while PCI relies on the $\delta$ variation. More precisely, the second derivative (or Laplacian) of the phase modulates the intensity after a finite propagation distance, and can be used for imaging the object microstructure. PCI requires a (partial) degree of spatial coherence for the x-ray beam, but depends weakly on spectral coherence, so there is no requirement for a monochromatic source [20]. Thus, the use of synchrotron radiation without a monochromator is possible for high-speed PCI.

Prior to PCI measurements at the APS, several of the samples were characterized by radiography-based tomography at Los Alamos National Laboratory. Specimens PBS-1 and ENG-3 were scanned with an in-house tungsten anode x-ray source operated at 150 kV. Multiple 2D radiographs were obtained via rotating the sample, and then converted to a 3D image via reconstruction.

PCI experiments were performed under ambient conditions at 32ID-B beamline of the APS. The experimental configuration is shown in Figure 2. The PCI method used a “white” beam which was transmitted through the composite material and single crystal samples and then imaged onto a camera. The storage ring was operating in the standard mode (24 bunches), with pulses of 40
ps duration spaced 153 ns apart [21]. The beam intensity and spectra were adjustable by varying the undulator gap with typical operation in the 11-30 mm range. Most of our measurements used an undulator gap of 20 mm. For this gap, the majority of the intensity was located in the first harmonic centered around 9 keV with a bandwidth of 0.4 keV FWHM, and the peak radiance was about $3 \times 10^{14}$ photons/s/0.1%bw (see Fig. 2b). Two electromechanical shutters (slow and fast) and a slit were placed between the x-ray source and the sample, conditioning the beam temporally and spatially for imaging and controlling the area of illumination on the sample. The slow shutter absorbs more than 99% of the power (to protect samples and diagnostics downstream from beam damage) and the beam goes through for a few milliseconds at a rate of 1 Hz. During this wide time window, the fast shutter produces a narrow time window of 5 µs for imaging. Both shutters were timed against a time-zero reference supplied by the synchrotron storage ring (RF signal), with appropriate delays controlled by a Stanford Research Systems (SRS) DG535 delay boxes. The illumination area on the sample was controlled with the slit(s).

A LAG:Ce scintillator was positioned downstream 120 mm away from the sample. A 45° mirror relayed the optical emission from the scintillator into the recording SensiCam camera (Cooke; 6.3 µm×6.3 µm pixel size, and 1280×1024 pixels), through a 10× microscope objective. The field of view on the sample was approximately 0.85 mm×0.65 mm. The beam was aligned with a foam target and spatial calibration was achieved by use of a 63.5 µm period gold grid. Resolution for the PCI setup was determined to be approximately 2-4 µm. The background intensity was about 80 counts (noise level).
Figure 2. (a) Schematic of the experimental setup for PCI at APS 32ID-B. The synchrotron storage ring was operated in the standard mode. The sample-scintillator distance ($L$) was 120 mm. (b) A simulated photon spectrum at 32ID-B for an undulator gap of 20 mm. Each division on the vertical axis represents $10^{14}$ photons/s/0.1% bandwidth.

4. Results

4.1 Single Material Characterization

Samples consisting of single crystals or single polymers were characterized in terms of the ability to resolve microstructure and signal to noise ratio (S/N). The strength of the signal is described here by the number of counts the detector records. PCI results are shown in Figure 3 for sucrose and acetaminophen single crystals and in Figure 4 for PMMA and Estane (in PBS-1 sample), and S/N is about 25.
**Figure 3.** PCI at the crystal edge for sucrose (a) and acetaminophen (b), showing clearly observable morphology, surface imperfections, and bulk defects. The intensity is about 2400 counts (a) and 2000 counts (b).

In Figure 3, the edges of the crystals are clearly defined and heterogeneities within the crystal are visible as well. For PMMA and Estane (Figure 4), suitable intensity was obtained throughout both specimens, and the images displayed in the figure were chosen to emphasize the ability to observe defects in high resolution. The images are from within the bulk of the polymers, showing internal crack branching and voids. Recall that PCI is a projection technique, so overlapping features are actually at different depths in the sample.
Figure 4. PCI within the bulk of PMMA (a) and Estane (b), showing cracking and voids respectively. The intensity is about 2000 counts.

4.2 Engineered Sample Characterization

The feasibility of studying interfacial phenomena in detail was assessed with the acetaminophen crystal-crystal samples (or “bicrystals”), ENG-1 and ENG-2. Figure 5 focuses on the bicrystal interface in the ENG-1 sample, showing sufficient contrast to resolve the boundaries of each crystal along with various bulk and surface imperfections such as curvature and growth spirals. Both crystals in ENG-1 show high roughness at the surface and noticeable bulk defects. The dark band at the surface of Crystal 2 was probably a result of slight tilting of the sample with respect to the beam axis.

Figure 5. Bicrystal interface resulting from bonding with water. The curvature of the surfaces prevented full bonding, but resolution of the two crystals is apparent. Surface defect structure is observed clearly.
The epoxy-bonded bicrystal ENG-2 was characterized with similar resolution to ENG-1 but provided additional insight into polymer-crystal delamination events, Figure 6. The large acetaminophen crystals had curved surfaces, and when the surfaces were joined by epoxy they appeared to relax over the duration of the cure time. This resulted in epoxy delamination from the crystal, simulating commonly observed crystal-binder delamination in PBX materials under small tensile loads [2].

**Figure 6.** Crystal-epoxy-crystal interface observed by PCI in ENG-2. Crystal 1 appeared to delaminate from the epoxy during the 24 hour cure time, possibly pulling the epoxy with it to create delamination from Crystal 2.

Fig. 6 appears to show delamination of the epoxy from both crystals. Certainly Crystal 1 has pulled away from the epoxy during the curing stage, but it appears to have initially pulled the epoxy off of Crystal 2 to form a buckle. Another possibility for the buckle formation is that Crystal 2 may have been moved sideways during the cure and caused a pileup of epoxy at the edge of the crystal. Either way, polymer-crystal delamination is well resolved with PCI.
ENG-1 and ENG-2 characterization proved the feasibility of imaging interfaces and small surface defects. However, crystal-crystal regions in typical PBX formulations are rarely as smooth as these engineered samples. ENG-3, the bicrystal with a machined trench, was a step towards real crystal surface imperfections. In order to understand the projection view obtainable with PCI, we first characterized the sample with radiographic microtomography. ENG-3 required doping to obtain contrast for the tomography, but unfortunately the nanoparticles tended to agglomerate when mixed in the epoxy. The disruption of x-ray signal caused by the large doping particles prevented the software from rendering a complete 3D image. However, we were still able to focus the x-ray signal at a particular depth in the sample, and we chose to focus on the longitudinal center of the trench. Figure 7 compares the tomography with PCI, showing the bicrystal interface and the trench in a side-on view. The tomography provided limited resolution of the composite structure and Bi$_2$O$_3$ particle distribution, while we were able to well-resolve Bi$_2$O$_3$ distribution in the epoxy-filled trench with PCI, as well as surrounding the crystals (not shown).

**Figure 7.** ENG-3 sample characterized with absorption microtomography (a) and synchrotron PCI (b). Doping with Bi$_2$O$_3$ provided absorption contrast in (a), showing both crystals as well as
highlighting the trench effectively. The Bi$_2$O$_3$ shows up as bright particles in the tomography slice but as dark particles in PCI.

It should be noted that the lateral spatial resolution is much higher for PCI (~2µm) than for tomography (~50µm), though the advantage of tomography clearly lies in the ability to focus on a depth in the sample rather than averaging signal as a projection. The resolution is a function of effective source size and phase contrast, both of which are superior in synchrotron PCI. In principle, PCI tomography can be done in such a way as to achieve sub-millimeter resolution with only a few seconds of exposure [22]. Alternatively, flash radiography can provide similar resolution at millisecond exposure times [23]. However, no technique currently exists that can provide full 3D phase information with micron spatial resolution and nano-to-microsecond temporal resolution. Within the limitations of current technology, synchrotron PCI appears to be the best option for high-speed study of these low-Z composites.

4.3 Plastic-Bonded Simulant Composites

We were able to observe crystals, polymer, voids, and cracks in the pressed Estane pellet, PBS-1. Half of the embedded crystals had been doped with Bi$_2$O$_3$ to assess the necessity of using dopant to achieve contrast. This sample had been previously characterized by x-ray tomography at LANL, and the transparency of the Estane allowed for some optical observation as well. Figure 8 is a comparison between x-ray tomography, optical microscopy and PCI.
Figure 8. X-ray tomography slice (a) compared with optical microscopy and synchrotron PCI (b) from specified locations in specimen PBS-1. “D” refers to doped crystals or interfaces, “C” refers to non-doped crystals or interfaces, and “V” refers to voids. Scale bars in the PCI images are 500 μm.

The dopant appears to be necessary to achieve contrast with the x-ray absorption tomography while it only mildly assists interfacial resolution in the PCI. Despite imaging through the thickness of the sample, PCI reveals fracture within the crystals and extensive void formation around the crystals. Both of these defect structures are likely caused by the high flow stress necessary to shape the original Estane particles into a pellet. PBS-1 was manufactured by pressing millimeter sized Estane particles around several acetaminophen crystals, rather than the wet agglomeration process described earlier, and this change in formulation conditions probably resulted in unusual stress conditions at the crystal-polymer interface. While the processing did not precisely replicate PBX formulation, the observations possible with PCI are both indicative of expected features and likely to be of equivalent utility in future measurements in actual formulations. Further, the excellent resolution observed implies that with proper experimental
approach, sample geometry, and fast detector advancements the photon flux is sufficient to perform dynamic observations of failure events with good resolution.

PBS-2 and PBS-3 were made with identical formulation parameters to PBX 9501 but were somewhat difficult to image. The results of both samples, doped and non-doped, are shown in Figure 9. It is instructive to compare the microstructure from Fig. 9 to the PBX microstructure from Fig. 1 in order to understand the imaging concerns.

![Figure 9](image)

**Figure 9.** Non-doped (a) and doped (b) PBS samples observed by PCI. Some outlines of crystals are visible but resolution of the microstructure is poor. Both samples were approximately 2 mm thick.

The lack of feature resolution in these samples likely has contributions from both x-ray scattering at thousands of interfaces within the sample and absorption of X-rays by the crystals (feature convolution). We determined that absorption of X-rays was a potential problem by analyzing the number of detector counts for each sample. Counts were as low as 300 per image; 1000-3000 was the targeted intensity. The overall absorption was not likely a function of the polymer since
PBS-1 had a much higher weight percentage of polymer and still gave satisfactory intensity. Also, the intensity through the sucrose samples was lower than expected for a low-Z material, so the high concentration of sugar in PBS-2 and PBS-3 probably caused most of the difficulty.

Noting that both the PBS samples were several millimeters thick, we addressed the problem by slicing off thin pieces with a razor. Figure 10 shows the same samples as Fig. 9 after slicing to a thickness of approximately 400 μm.

**Figure 10.** Thin PBS samples observed by PCI. Several large facets as well as multiple small crystals are visible in the undoped specimen (a), while the doped specimen (b) appears to show crystal-binder agglomerates rather than individual crystals.

The thinner samples provided much better absolute intensity (≈1500 counts). Most of the contrast in the non-doped composite (Fig. 10a) arises from the small crystal interfaces but several large crystals are mostly visible. The doped composite reveals a different microstructure previously unobservable. The dopant appeared to surround the molding prills, the crystal-polymer agglomerates, rather than migrate to the crystal-polymer interface. This conclusion was
reached by comparing the observed microstructure to the faceted crystal morphology from Fig.1. The dopant also showed a tendency to clump; note that the Bi$_2$O$_3$ was a nanopowder before mixing with the PBS molding prills but regions of high concentrations in Fig. 10b are hundreds of microns across. This indicates that the presence of the powder may have affected the pressing behavior of the PBS agglomerates, or that the pressing process induces much less polymer flow around crystals than has been previously suspected. Contrasting doped vs. non-doped samples may be of use to study the effect of changing processing parameters on resulting composite microstructure.

5. Implications for dynamic experiments

We found that single materials and engineered composite samples could be studied in great detail with the current x-ray detector setup at APS. High spatial resolution was achieved even at very fast (5 μs) exposure times. We clearly observed defects such as internal cracks, voids, air bubbles, surface imperfections, and polymer delamination.

Our high-speed PCI measurements at ambient conditions show promises as well as limitations in resolving in situ microstructure in dynamic experiments at APS-type synchrotrons. The key parameter is S/N, determined by the exposure time as required by specific dynamic experiments, beam characteristics (mostly synchrotron operation mode), sample type, and probing thickness, as well as scintillators and x-ray cameras. For the current detector system, a minimum S/N of 3 corresponds to $I_{\text{min}}=240$ counts. We easily exceeded this minimum with 5 μs exposure times for our simulated PBX samples. However, the feasibility of keeping an adequate S/N when trimming the exposure time to capture shock events (~0.5 μs) needs to be discussed.
We take the nominal intensity in current setup as \( I_0 = 2500 \) counts for 5 \( \mu \)s exposure time in the standard mode (102 mA in 24 bunches during 3.68 \( \mu \)s; the bunch separation is 153 ns). It requires about 3 bunches in the standard mode to obtain \( I_{\text{min}} \); 3 bunches in the standard mode correspond to a camera gate width of 207 ns. Thus, for the current detector and the standard mode, the “exposure time” (image integrated over this period from multiple bunches) will be at least 0.2 \( \mu \)s. The standard mode operation should be sufficient for study of a wide range of dynamic experiments, but APS also offers an alternative operation mode. The hybrid or singlet mode at APS has different time structure of the probing beam. In the hybrid mode, a singlet pulse (16 mA, 65 ps pulse duration) is separated from septuplet pulses (86 mA and 470 ns in total) by 1.594 \( \mu \)s on either side. The singlet is more desirable for time resolution due to the 65 ps duration, but synchronizing the dynamic event with the pulse is likely to be very difficult. Additionally, achieving sufficient S/N requires capturing information from more than one singlet, which will require several \( \mu \)s exposure times. The singlet mode is likely to be most useful for dynamic experiments at medium to low strain rates (\( 10^2 - 10^4 \) s\(^{-1}\)). Improving the detector sensitivity or increasing photon fluxes may reduce the exposure time for both standard and hybrid modes at APS to allow for higher strain rate experiments.

One potential concern for dynamic experiments was the difficulty of imaging the simulated PBX composites at thicknesses greater than 1 mm. Sufficient resolution of the microstructure was not reached even with 400 \( \mu \)m thick samples. Adequate sample dimensions are necessary to achieve a sufficiently long, stable state (e.g., supported shock duration) and thus the required exposure time for PCI. However, sample dimensions and exposure times for dynamic study will be
tailored to specific loading scenarios, such as drop weight, split Hopkinson pressure bar or Kolsky bar, or gas gun experiments [24-26]. For non-shock strain rate experiments, meaning slower dynamic loading, the exposure time can be correspondingly longer. It is possible that complex microstructures could still be studied with PCI under such conditions. For our purposes, initial efforts on dynamic PCI should be focused on simple microstructures or engineered interfaces with elemental deformation processes.

6. Conclusions

PCI has proven to be quite useful for imaging non-transparent simulated plastic-bonded explosives. PCI is superior to absorption radiography in terms of contrast, effective resolution and doping requirements. Doping is not necessary to achieve contrast between similar materials or within composites but can show a different structure (i.e. structure of molding prills rather than crystals). We demonstrate that sufficient contrast and intensity can be achieved for low-Z composites with the APS X-ray source in the standard operation mode and that dynamic study at high strain rates is feasible. Synchrotron PCI should be able to reveal the response of preexisting microstructure to shock loading. Specifically, void nucleation and collapse, fracture delamination, grain boundary/interface deformation, and hot spot formation may be studied with high temporal and spatial resolution. In addition, PCI may be useful for imaging mechanical or chemical behavior of other low-Z composites, statically or dynamically, even at microsecond time scales.
