Eight aggregates were defined and data collection locations were selected to resolve the subordinate questions and decisions. In aggregates where there were existing data and known contaminant sources, wells were placed where they were most likely to encounter contaminants and to assess contaminant transport pathways. In aggregates with little existing hydrologic data and known contaminant sources, wells were located proximal and down gradient from contaminant sources. In aggregates where there were little existing data and small or no contaminant sources, wells were placed to reduce uncertainties in the hydrologic setting and to confirm the assumption of no groundwater impact.

The original Hydrogeologic Workplan proposed to characterize the hydrogeologic setting by drilling, logging, installing, and sampling wells to the regional aquifer without installing separate intermediate-depth wells. This approach was expected to provide the greatest amount of characterization data and was agreed to by NMED, as documented in a letter sent to NMED (LANL 1996b). This approach was formulated based on the following technical rationale:

- The presence of intermediate zone(s) is controlled by geologic structure and the geology across LANL is extremely variable. Understanding the geologic setting from the surface to the regional aquifer is more important in predicting flow than measurements in individual intermediate zones.
- If a well were installed at the first intermediate zone encountered, there would be a gap in the information between the upper intermediate zone and the top of the regional aquifer. Furthermore, wells installed in the first intermediate zone will not provide any information on the underlying less permeable perching layer. The characteristics of the perching layer must be understood in order to assess the impact to the regional aquifer. The perching layer stratigraphy is as important to evaluating potential pathways as the hydrologic characteristics of the saturated zone itself.
- The data collection described in the Hydrogeologic Workplan is intended to characterize the hydrogeologic setting to a sufficient degree to develop an adequate detection monitoring system or groundwater monitoring waiver, if appropriate. Wells that may be needed to monitor the intermediate zone(s) will be considered as part of the monitoring system design.

1-A-3.1 Revision to Hydrogeologic Workplan Data Collection Approach

The characterization approach was modified as the Hydrogeologic Workplan was implemented. A major drilling program change was prompted by an NMED letter (NMED 1999) with two key points: (1) water samples taken from boreholes during the drilling operation would not be adequate for regulatory decisions; and (2) perched zones did not have to be sealed off during drilling, but could be left open until the well was constructed. The practical result of these requirements was that intermediate perched zones could not be characterized by obtaining one sample during drilling. Instead, a dedicated sampling location must be installed to characterize the intermediate perched zones over time. Initially, wells that encountered intermediate perched zones were built with multiple completions. Eventually separate intermediate wells were constructed to be able to monitor the intermediate perched zones. The second point in the 1999 NMED letter, to be able to leave intermediate perched zones open, allowed the wells to be drilled faster because there was no longer a need to telescope down well casing sizes to seal off intermediate perched groundwater zones.

Another modification from the Hydrogeologic Workplan was the use of fluids in drilling. The original Hydrogeologic Workplan called for drilling with no additives in order to collect pristine samples while drilling. The earliest wells were drilled using air-rotary drilling methods with casing advance and the minimal use of fluids other than air. Because of significant problems associated with stuck casing, unstable boreholes, and lost circulation, small amounts of drilling fluids were used to improve lubricity, borehole stabilization, and cuttings circulation. Continuing drilling problems made total reliance on air-rotary drilling with casing advance impracticable for meeting drilling objectives. It became apparent that the depth of the wells and the difficult drilling environment required that more drilling techniques be added to the drilling "tool box" in order to respond to the complex hydrogeologic conditions that characterize the Pajarito Plateau. All of the drilling methods used at LANL are used in standard environmental industry practice and are described by the American Society for Testing and Materials (ASTM). Table 1-A-2 briefly describes the drilling methods used since the beginning of the drilling program.

1-A-3.2 Alluvial Groundwater Investigations

Beginning in the mid-1990s, detailed investigations were begun for the ENV-ERS Project, which is driven by the Laboratory's HSWA module to the RCRA operating permit. The first watershed investigation to be implemented was in the Los Alamos and Pueblo Canyon watershed to fulfill request for information requirements presented in the Task/Site Work Plan for Los Alamos and Pueblo Canyons, OU 1049 (LANL 1995b) and the subsequent addendum, Surface Water and Alluvial Groundwater Sampling and Analysis Plan (LANL 2002). The watershed-scale investigations conducted under the ENV-ERS Project are designed to collect data sufficient to evaluate human-health and ecological risk at a watershed scale. In accordance with existing canyons work plans, the Compliance Order on Consent, and the Federal Facility Compliance Agreement for storm water, surface water and alluvial groundwater investigations are conducted in a coupled manner in order to facilitate the development of conceptual models of the relationship between these waters.

Table 1-A-2.
Drilling Methods Used for Hydrogeologic Characterization Wells at Los Alamos National Laboratory

Drilling Method	Description	Benefits	Drawbacks
Air rotary ASTM D5782-95; D5781-95 (ASTM, 2000a; ASTM, 2000b)	A drill pipe or drill stem is coupled to a drill bit that rotates and cuts through soils, alluvium, and rock. The cuttings produced from the rotation of the drilling bit are transported to the surface by compressed air or by compressed air augmented by municipal water mixed with drilling additives. In conventional air-rotary drilling, the compressed air is forced down the borehole through the drill pipe and returns to the surface up through the annular space. In reverse air rotary, a dual tube drilling system is used and drilling fluids are forced down the outer tube and return up the center tube, where the cuttings are discharged through a cyclone velocity dissipater. The circulation of drilling fluids not only removes cuttings from the borehole but also cools the drill bit.	The air rotary drilling method, employed in an open hole, is the fastest and least expensive drilling method in the unsaturated zone. It is best suited for stable, hard rock formations with good circulation characteristics (in which there is minimal loss of fluids into the formations). Open hole drilling allows for the collection of an extensive suite of geophysical logs for the characterization of hydrogeologic properties.	Experience gained in the early part of the drilling program showed that air rotary drilling in an open hole is not always a suitable method for drilling at depths greater than 150 feet below the regional aquifer water table. The use of municipal water with drilling additives is almost always required to improve borehole stability and circulation of cuttings. Use of these drilling fluids can alter the natural properties of the rocks and it is not possible to collect pristine water samples while drilling. Generation of dust at the surface is a problem unless dust-suppression equipment is used and/or municipal water is added to the circulation fluid.
Casing advance ASTM D5876-95 (ASTM, 2000c)	Air-rotary drilling using an under reamer cutting system (rotary bits or downhole hammer) to create a hole large enough for a heavy-walled casing to slide down behind the drill bit. The casing is advanced simultaneously while drilling the hole. Compressed air or compressed air augmented by municipal water mixed with drilling additives is used to remove the cuttings from the bottom of the borehole. When the borehole has reached total depth, the well is constructed inside the heavy walled casing, as the casing is incrementally removed.	The drill casing stabilizes the borehole when drilling through poorly consolidated materials and improves circulation in highly porous or fractured rocks. The cased hole provides a stable environment for the construction of the well. There is relatively little disturbance to the borehole walls and relatively undisturbed samples of rock and water are obtained during drilling.	The heavy-wall casing frequently becomes stuck and is difficult to extract from the borehole. Casing that can not be extracted must be abandoned in the hole, possibly impacting the use of some well screens. The cost is high and drilling rates are often very slow. The use of municipal water with drilling additives is almost always required to provide lubricity between the casing and the borehole wall and to improve borehole stability and the circulation of cuttings. Use of heavy-walled casing severely limits the geophysical methods that can be used for hydrogeologic characterization.
Mud rotary ASTM D5783-95 (ASTM, 2000d)	A bit is rotated to cut through the rock while mud is the circulating fluid pumped down through the drill pipe and returned back up the borehole through the annular space. The mud-filled hole stabilizes the borehole wall and cools the drill bit. Circulation of the mud carries the cuttings up to the surface.	Rapid and effective drilling methods. Can be used to maintain borehole stability in poorly consolidated sediments of the saturated zone. Open hole drilling allows for the collection of an extensive suite of geophysical logs for the characterization of hydrogeologic properties.	Does not work well in vadose zone due to lost circulation zones in fractured basalts and in highly porous tuffs and sediments. Masks the recognition of water-bearing zones while drilling. Slow circulation of mud mixes cuttings from throughout the borehole, hampering geologic characterization. Addition of drilling muds and fluids changes the geochemical environment around the borehole. Requires extensive development to remove residual muds and drilling fluids, and to restore the aquifer's hydraulic and geochemical properties to natural conditions.

The scope of investigation in the Los Alamos/Pueblo watershed (other watershed work plans have similar scope) consisted of 4 sampling rounds collected through one year across a representative range of hydrologic conditions (e.g., higher water levels and more extensive saturation typical of spring snowmelt conditions; and low groundwater levels that commonly occur in the fall), detailed water-level measurements collected using dedicated pressure transducers, measurement of field parameters, a water balance study, and field observations on extent and persistence of surface water. These data were used to develop a conceptual model to describe the occurrence and temporal context of groundwater contamination in support of the risk assessment. The report for the Los Alamos and Pueblo Canyon investigation was submitted to the NMED in April, 2004. The Mortandad Canyon investigation is underway, and the report is scheduled for completion in 2006. Subsequent watershed-scale investigations will be completed in order of priority.

1-A-4. Independent Peer Review of the Hydrogeologic Workplan

In 1999, an External Advisory Group (EAG) was formed to provide an independent review of the implementation of LANL's Hydrogeologic Workplan. The EAG consisted of six members with diverse technical and professional backgrounds to provide a broad technical and managerial review of LANL's Hydrogeologic Workplan activities and methods. The EAG was provided semi-annual updates on the program status. The EAG provided a report of findings and observations based on the semi-annual reviews (External Advisory Group 1999a, 1999b, 2000a, 2000b, 2001a, 2001b, 2002; External Evaluation Group 1998). In response, action plans were developed that specified how the recommendations of the EAG were incorporated into the program.

In addition to the semi-annual reviews, the EAG provided technical assistance when requested. In FY99, two EAG members provided invaluable assistance in repairing the well R-25 collapsed screen #3. Numerous problems encountered in the repair process were overcome with the advice and guidance of the EAG members. The "hands on" assistance was critical in completing the characterization well.

1-A-5. Outreach Activities

The original Hydrogeologic Workplan (LANL 1998) specified a communications approach that included three quarterly meetings, one annual meeting, and an annual status report to update regulators on the characterization progress. The primary purpose of the quarterly meetings was to report on progress and findings from the previous quarter. The annual meeting was intended to provide more of a synthesis of data collected in the previous year and to allow regulators to provide their input to the planned activities for the coming year. One objective of the annual meeting was to reach a DOE, LANL, NMED consensus on the activities for the following year in time to influence budget requests. The annual report was published as a prelude to the annual meeting and provided the written synthesis of the data collected and interpreted over the year. The first annual meeting was held in March 1998 and participants were limited to representatives of the DOE, LANL, and NMED. Annual meetings were held in 1999, 2000, 2001, 2002, 2003, 2004, and the last annual meeting was held in 2005.

Extensive information has been presented and discussed with regulators and the public in several ways since the Hydrogeologic Workplan was completed in 1997 (Table 1-A-3):

- Three quarterly meetings and one annual meeting held every year (27 documented meetings) with distribution of meeting minutes to an extensive mailing list
- Annual status reports summarizing the work accomplished in the previous year
- Well completion reports
- Geochemistry reports
- Hydrologic testing reports
- Water quality data, which are available over the internet at http://wqdbworld.lanl.gov.
- Annual environmental surveillance reports, which provide the analytical results of surface water and groundwater sampling at LANL and in northern New Mexico.

APPENDIX 2-A. GEOLOGIC INFORMATION USED TO DEFINE THE CONTROLS ON HYDROLOGY

2-A-1. Lithologic Information from Cuttings and Core

Drill cuttings and core were collected in all boreholes to meet the regional hydrogeologic characterization requirements described in Section 4.2 of the Hydrogeologic Workplan (LANL, 1998). Cuttings and core provide the most direct evidence for the vertical distribution of hydrogeologic units at each borehole. Correlations of rock units among boreholes are key components of the site-wide 3-D geologic model for the plateau.

Drill cuttings were the most common type of geologic samples produced during the drilling program. Approximately 500 to 700 ml of bulk drill cuttings were collected every 5 ft, as conditions permitted, to the total depth (TD) of each boring. Cuttings were stored in plastic bags labeled with the well name and footage range representing the depth interval at which the cuttings were collected. A subset of unsieved and sieved samples were collected from each cuttings interval and stored in plastic chip trays for geologic examination. The quality and representativeness of cuttings depended on a number of drilling variables including type of circulation fluids used (air, water, foam, mud), circulation type (conventional, reverse), and drill-bit pressure.

Core was collected from dedicated core holes where it was often paired with deeper drill holes. Core was also collected from selected intervals in some regional aquifer boreholes. Core was collected to fulfill a number of characterization objectives, including:

- Geologic characterization of groundwater-bearing zones and aquitards in perched groundwater systems
- Collection of moisture-sensitive samples for hydrologic and chemical analyses of vadose-zone samples (e.g. moisture, anions)
- Collection of intact rock samples to determine hydraulic properties of selected hydrogeologic units.

Rock lithologies, alteration features, and stratigraphic contacts for each borehole are summarized in lithologic logs based on visual examination of cuttings and core. A small subset of core and cuttings was selected for additional characterization to better understand alteration features relevant to rock-water interactions and to aid correlation of rock units between boreholes. The additional characterization primarily consisted of X-ray diffraction for mineralogy, X-ray fluorescence for rock chemistry, thin-section petrography, and $^{40}Ar/^{39}Ar$ age dating. The lithologic logs also incorporated information about stratigraphic contacts and rock properties based on interpretations of borehole geophysical logs.

Core and cuttings are currently archived at the ENV Division Sample Management Facility located at Technical Area 3, building 03-0271-101. All borehole materials are stored in core boxes labeled with the well name, box number, and footage range for the box.

2-A-2. Borehole Geophysical Data

Borehole geophysical data were collected to determine the geologic and hydrologic characteristics of the vadose zone, perched saturated zones, and the regional aquifer as specified in Section 4.1.6 of the workplan. A listing of geophysical logs collected during installation of Hydrogeologic Workplan wells is given in the well completion reports associated with those wells. Borehole geophysical data were obtained from two sources. Laboratory/contractor personnel collected caliper, spontaneous potential, single-point resistance and induction, and natural gamma radiation logs using the Laboratory's geophysical logging equipment, usually during breaks in the drilling process when conditions permitted the collection of open-borehole data. A wire-line logging service was contracted to obtain a more extensive suite of borehole geophysical logs once the borehole reached total depth.

The number and types of contracted wire-line geophysical logs varied as a function of borehole condition, the presence or absence of drill or well casing, whether the borehole was air or fluid filled, and technical issues addressed by a particular logging run. Drilling conditions determined whether the borehole was open or cased at the time of logging. Table 2-A-1 gives the typical suites of logs that have been run by wire-line logging services in cased and open boreholes. General logging information and borehole conditions at the time of logging were documented by site personnel.

Preliminary results of geophysical logs were generated in the logging truck at the time the geophysical services were performed. These preliminary logs were used by contractor, DOE, and LANL personnel to help select well screen locations and to evaluate borehole conditions prior to well construction.

The geophysical contractor reprocessed the field measurements to correct for borehole and formation environmental conditions, to perform an integrated analysis of the log measurements so that they were all coherent, and to combine the logs into a single presentation enabling integrated interpretation. The contractor then prepared an interpretive report that was included as an appendix in the well completion reports. The interpretive report includes information about the hydrogeologic characteristics of the rocks penetrated by the boreholes, moisture distributions as a function of depth, the location of the regional water table, borehole diameter, deviation as a function of depth, and degree of drilling fluid invasion. Depending on the suite of logs collected, the interpretive report may include information about

- total and effective water-filled porosity and pore size distribution, from which an estimate of hydraulic conductivity is made,
- bulk density and photoelectric effect, the latter of which is particularly sensitive to lithology,
- electrical resistivity at multiple depths of investigation,
- concentrations of a number of elements,
- spectral natural gamma ray, including potassium, thorium, and uranium concentrations,
- bedding orientation and geologic texture,
- borehole inclination and azimuth, and
- borehole diameter.

2-A-3. Borehole Video Logs

Borehole video logs were run in open boreholes to obtain lithologic information and to help determine stratigraphic contacts for the geologic units penetrated, to allow visual examination of borehole walls for evidence of perched saturation, and to document water levels in the boreholes. Video logs also were run when wells were completed to document the as-built condition of installed well components. Additional videos were sometimes run during and after well development to assess the effectiveness of development techniques. Finally, the borehole video logs were used during drilling operations to assess problematic borehole conditions and to guide fishing operations for tools and equipment lost downhole.

One of the principal uses of the borehole video logs was to identify potential groundwater pathways. For example, when used in conjunction with geophysical logs, video logs were an important method for locating highly porous interflow breccias sandwiched between massive basalt flows. These interflow breccias were important for determining the locations of perched zones in some boreholes. The video logs also showed whether the porosity of these interflow breccias was open or modified by deposition of extensive secondary clay minerals. Fractures are potential pathways in the massive flow interiors. Fracture density, fracture dips, and open verses sealed fractures were assessed using video logs.

2-A-4. Surface Geophysical Data

Surface geophysical data were used to help constrain the site-wide geologic model. These data include regional gravity data, airborne electromagnetic data, high-resolution resistivity, and magnetotellurics. Gravity data were used to help define regional structure beneath the Pajarito Plateau. Airborne electromagnetic data, high-resolution resistivity, and magnetotelluric data were used to focus groundwater investigations by defining the conductivity structure beneath the plateau. The remainder of this section describes the airborne electromagnetic data in more detail.

An electromagnetic (EM) and magnetic survey was flown over the Pajarito Plateau in early September 2001 by the Fugro Airborne Surveys Corporation on behalf of LANL. A total of 762 line kilometers of MegaTEM® time domain EM data and magnetic data were collected. Flight lines were spaced at 333.3 ft (105 m) within the Laboratory boundaries, and at 666.7 ft (210 m) in buffer zones adjacent to the Laboratory, oriented N20E: with tie lines at an approximate 2000-meter spacing. Because of security constraints stemming from the events of September 11, 2001, flight lines in the western 20% of the Lab, and the two tie lines in the northern portion of the Laboratory were not flown.

The contractor provided maps of Residual Magnetic Intensity (RMI), apparent conductance and conductivity depth slices at various depths, multiparameter profiles with conductivity-depth-transform (CDT) sections for flight lines and digital archives of line and grid data. The digital EM data were analyzed at a later time (end of FY01) by Condor Consulting, Inc. This analysis resulted in two additional models of CDTs along the flight paths. All of the processing assumed a “layered-earth” model, and all of the inversions were restricted to single points/multiple depths (1-D), multiple depths along individual flight lines (2-D), or a constant depth on multiple flight lines (2-D); there was no true 3-D inversion performed on the data set. Data from the existing

3-D geologic model, identifying zones of expected similar hydrologic properties, were provided to Condor and are part of the initial data analysis. Borehole geophysical logs were also provided to Condor to assist in calibrating their models. The results of all three models for each flight line are available. At some future time, a constrained 3-D inversion, utilizing the 3-D hydrogeologic model, may allow better resolution of the conductance inversion results.

Visual correlation of conductance and observed groundwater can be obtained through study of the "multiplots" of the flight lines closest to groundwater occurrences. An effort has been made to allow creation of 3-D conductance models for each of the CDT data sets. Interpolation of flight line data is accomplished through scaled interpolation within an oriented ellipsoid that samples a similar number of points in the directions: vertical, along-flight-line, and between-flight-line. Many 3-D visualization packages are capable of displaying and scaling 3-D grid data. As much of the error/uncertainty of the conductance model occurs in the depth/thickness value, real-time scaling and offsetting the z-axis of the conductance grid can allow correlation with known groundwater locations obtained from drill holes; and thus allow a projection/extrapolation of the groundwater surface beyond the limits of direct observation.

The two tie lines of the survey provide conductance signatures that correlate well with the major faults in the western portion of the Laboratory and could perhaps provide some information regarding their dips. These survey lines indicate other localities with signatures similar to those of the mapped faults, which may indicate buried faults or conductive fracture zones further to the east.

2-A-5. Drilling Information

Observations about drilling characteristics by the drillers and on-site geologists contributed to understanding the hydrogeology of the boreholes. These observational data were recorded in field logs, and they provided supplemental information that aided the interpretation of hydrogeologic data from other sources such as cuttings and geophysical logs.

Because of the heterogeneous nature of the rocks beneath the plateau, major lithologic and stratigraphic contacts were commonly marked by significant changes in drill penetration rates. Drilling rates were affected by a number of factors, but chief among them was the competency of the rocks being penetrated. Hard rock units such as strongly welded tuffs, lava flows, and boulder-rich fanglomerate deposits were characterized by slow drilling rates, whereas less competent rocks such as nonwelded tuffs and poorly indurated sands, silts, and clays drilled more rapidly. For example, drill penetration rates normally decreased downhole when going from the nonwelded tuffs at the base of Qbt 3 into the welded tuffs at the top of Qbt 2 and from the Guaje Pumice Bed into Puye Formation and/or Cerros del Rio basalt.

Information about borehole stability and lost-circulation zones also provided important site-specific information about subsurface conditions. For example, open borehole drilling at R-22 was complicated by caving conditions and by difficulty in maintaining free rotation of the drill string though thick sequences of basalt. Normally, the interiors of basalt flows are strongly competent and yield gun-barrel smooth boreholes, but the conditions at R-22 suggested that loose blocks of basalt were caving into the borehole and binding up the drill string. Subsequent

borehole video logs showed that dense networks of fractures intersected the R-22 borehole resulting in an unstable borehole. Similarly, lost circulation zones generally indicated that drilling fluids had escaped into highly porous fractures or scoria zones intersected by the borehole. At R-34, significant zones of lost circulation were associated with thick beds of loose basaltic scoria. Some cavities observed in borehole videos might be small-scale lava tubes or caverns similar to those known to occur in the Cerros del Rio volcanic field east of the Rio Grande.

Important information about water-bearing strata was obtained when drillers noted changes in the drilling fluids circulating through the borehole. Perched water and the top of the regional zone of saturation were readily recognized when water and wet cuttings were returned to the surface using air-rotary drilling methods. Water-bearing zones were identified even when using fluid-assisted air-rotary methods that involved the use of air, municipal water, foam, and other additives for circulation. When using such methods, surplus production of water and thinning of drilling foam often was associated with the intersection of groundwater.

2-A-6. Data Generated by Other Projects

Numerous local and regional mapping projects and geological studies have provided important information supporting development of geologic conceptual models and digital realizations of these models. Pioneering work by geologists of the U.S. Geological Survey (USGS) helped define the tectonic setting and the major hydrogeologic units of the region (Smith, 1960a and 1960b, Griggs, 1964; Smith and Bailey, 1966; Bailey et al., 1969; Smith et al., 1970). Regional and local studies of rock unit ages, many of which were supported by the Laboratory, provided a time scale to calibrate the timing of the volcano-tectonic development of the site: faulting and volcanism, and emplacement of the resultant volcanic flows and sedimentary units (Gardner and Goff, 1984, Gardner et al., 1986; Loeffler et al., 1988; Turbeville et al., 1989; Izett and Obradovich, 1994; Spell et al., 1990; Spell and Harrison, 1993; Spell et al., 1996; Toyoda et al., 1995; McIntosh and Quade, 1995; WoldeGabriel et al, 1996; Reneau et al., 1996; Smith, 2001; WoldeGabriel et al., 2001; Goff and Gardner, 2004). Understanding the nature of the evolving tectonic regime allowed development of models to define the conceptual, spatial distribution of hydrogeologic units, as well as explanations of their post-deposition evolution.

The New Mexico state mapping program, supported by the USGS and the New Mexico Bureau of Geology and Mineral Resources, with help from LANL scientists, produced 1:24,000-scale, surface geologic maps and accompanying cross sections for the Frijoles (Goff et al., 2002), White Rock (Dethier, 1997), Puye (Dethier, 2003), and Guaje Mountain (Kempter and Kelley, 2002) quadrangles. These four maps encompass the Laboratory site with a significant buffer zone, allowing the integration of site and regional geologic features. Other geological maps, some with cross sections, covering portions of the LANL include those by Baltz et al., (1963); Goff et al., (1990); Rogers, (1995); Vaniman and Wohletz, (1990); Reneau et al., (1995); Goff, (1995); Lewis et al., (2002); and Lavine et al., (2003).

Española Basin workshops were hosted annually by the Española Basin Technical Advisory Group and sponsored by the U.S. Geological Survey, the New Mexico Bureau of Geology and Mineral Resources, Los Alamos National Laboratory, and the city of Santa Fe. These workshops

were important forums for disseminating results of ongoing technical studies of the hydrogeologic framework of the Española Basin.

The seismic hazards program at LANL was an important source of information about faults and fractures in the vicinity of the Laboratory (Gardner and House, 1987; Gardner et al., 1990, 1993, 1999, 2001; Lewis et al., 2002; and Lavine et al., 2003). Their high-resolution, surface mapping of subunits of the Bandelier Tuff provided new information about the distribution and nature of faulting on the Pajarito Plateau and made estimates about amounts and rates of offset of geologic units. Numerous other Laboratory projects and programs helped to develop geologic information supporting geologic conceptual models. The Environmental Restoration project funded numerous projects as part of its RCRA facilities investigations that provided information about geologic framework of the site and hydrologic properties of geologic units.

Students and their advisors from the graduate programs from the University of New Mexico, New Mexico State University, and New Mexico Institute of Mining and Technology have provided additional hydrogeologic information for the Jemez volcanic field and Española Basin. Studies by graduate students from the University of Texas (e.g., Turbeville et al., 1989) were especially useful for understanding the Puye Formation.

Table 2-A-1.
Typical Wire-Line Geophysical Logging Tools

Cased Hole	Cased Hole	Open Hole	Comments
Array Induction Tool (AIT)		X	Measures open-hole formation conductivity with multiple depths of investigation at varied vertical resolution
Triple Litho Density Tool (TLD)	X	X	Evaluates formation porosity where grain density can be estimated
Combinable Magnetic Resonance Tool (CMR)		X	Provides information on water content and relative abundance of hydrous minerals and capillary-bound versus mobile water
Natural Gamma Tool	X	X	Used to distinguish lithologies by their gross gamma signature; also used to calibrate depth of other geophysical tool readings
Natural Gamma Ray Spectrometry Tool (also called the spectral gamma tool)[1]	X	X	Used to distinguish lithologies where formations vary in relative and overall concentrations of potassium, thorium and/or uranium
Epithermal Compensated Neutron Log (CNL)	X	X	Measures moisture content in unsaturated conditions and porosity in saturated conditions
Caliper		X	Measures rugosity of borehole wall
Fullbore Formation Microimager (FMI)		X	Provides high-quality image of borehole based on electrical properties; used to determine lithologies, bedding attitudes, fracture characteristics, and borehole deviation
Elemental Capture Spectrometer (ECS)	X	X	Determines formation lithology from bulk geochemistry; used primarily to determine elemental concentrations of silicon, calcium, iron, titanium, and gadolinium

[1]A total gamma log was collected with each geophysical suite to correlate separate logging runs within a borehole.

APPENDIX 2-B. PERCHED WATER OCCURRENCES

This appendix documents the field observations of the 33 occurrences of perched groundwater detected in 29 boreholes across the Pajarito Plateau. Characteristics of deep perched groundwater zones encountered in wells on the Pajarito Plateau are listed in Table 2-B-1.

In the western part of Los Alamos Canyon, perched groundwater occurs at depths of 89 to 137 m (293 to 450 ft) in the Guaje Pumice Bed and in underlying Puye Formation fanglomerate. Saturated thicknesses for these occurrences range from about 6.7 m (22 ft) in the west to about 1 m (3 ft) in the east. These groundwater occurrences in the Guaje Pumice Bed may represent a related groundwater system because of their similar geologic and geographic settings, however, in one well, R-7 (Figure 2-37), perched groundwater occurs immediately beneath the Guaje Pumice Bed, in the underlying Puye Formation. The east-west extent of perched groundwater in the Guaje Pumice Bed is about 5.6 km (3.7 mi). Little is known about the extent of perched groundwater beneath the adjacent mesas, but a dry borehole extending to the Guaje Pumice Bed (borehole 21-2523) suggests that saturation does not extend beneath the mesa north of Los Alamos Canyon. The perched groundwater is free of contamination in the central part of the canyon (e.g. well LAO(I)A-1.1) but contained 3000 pCi/L tritium in 1995 at LADP-3 (Broxton et al, 1995), the easternmost well penetrating this groundwater body. The movement of groundwater in the Guaje Pumice Bed may be controlled by paleotopography on top of the underlying Puye Formation. Structure contours indicate that the down-dip direction for the base of Guaje Pumice Bed beneath Los Alamos Canyon is towards the south and east (Section 2.2.9).

Eastward in Los Alamos Canyon, perched zones are generally thicker and occur at multiple depths. In well R-9 for example, three perched systems were encountered: 1) in the central part of the Cerros del Rio basalt, 2) in the basal part of the Cerros del Rio basalt, and 3) in pumice-rich deposits in the lower part of the Puye Formation. Saturated thicknesses for the top and bottom zones range from about 13.7 to 31.4 m (45 to 103 ft), and the middle zone was 2.1 m (7 ft) thick. The top and middle perched zones in R-9 are also present in well LAWS-1, located 396 m (1300 ft) to the east, but their lateral extent is likely to be much greater. The occurrence of more extensive perched groundwater in the eastern part of Los Alamos Canyon may be due to enhanced infiltration where the canyon floor is underlain by Puye fanglomerate and Cerros del Rio basalt rather than by Bandelier Tuff. Tritium activities of 69 to 246 pCi/L for these perched groundwaters are elevated relative to the cosmogenic baseline of 1 pCi/L, suggesting that these zones contain a component of young water that postdates the advent of atmospheric nuclear testing 60 years ago (Longmire, 2002).

Table 2-B-1.
Characteristics of Deep Perched Groundwater Zones Encountered in Wells on the Pajarito Plateau

Watershed	Well Name, Borehole Depth (ft), Surface Elev. (ft)	Depth to Water (ft)	Saturated Thickness (ft)	Groundwater Host Rock	Nature of Perching Layer	Anthropogenic Chemicals Detected	Comments
Pueblo Canyon	TW-2a 133 6646	110	>23	Puye Fm. fanglomerate	Within Puye Fm. fanglomerate; perching lithology not known	Tritium, nitrate	A single-screen well was installed in this zone (Griggs, 1964, Purtymun, 1995).
Pueblo Canyon	R-5 902 6473	~380	~37	Puye Fm. dacitic sands and gravels mixed with 5-15% rounded quartzite and granite river gravels	Within Puye Fm. fanglomerate; perching lithology not known	Nitrate, fluoride, chloride, uranium, and sulphate	A canyon-floor well was installed with four isolated screens (LANL, 2003). Screen #2 is complete in this perched zone. The vertical extent of this zone is poorly known.
Pueblo Canyon	TW-1a 225 6370	188-225 (?)	±37 (?)	Interflow breccia and siltstone in Cerros del Rio basalt	Possibly unfractured massive basalt	Nitrate, phosphate, chloride, boron, and uranium	Groundwater was first encountered near the top of Cerros del Rio basalts in a zone from 212- to 215-ft-deep (Griggs, 1955). Groundwater may be confined because the water level stabilized at 188 ft (Purtymun, 1995). Well screen placed from 215 to 225 ft deep.
Pueblo Canyon	POI-4 181 6372	160	>21	Cerros del Rio fractured basalt	Confining layer not penetrated	Nitrate, phosphate, chloride, boron,	Groundwater occurs in massive basalt cut by high-angle fractures. A single-screen well was installed in this zone.

Table 2-B-1.
Characteristics of Deep Perched Groundwater Zones Encountered in Wells on the Pajarito Plateau (continued)

Watershed	Well Name, Borehole Depth (ft), Surface Elev. (ft)	Depth to Water (ft)	Saturated Thickness (ft)	Groundwater Host Rock	Nature of Perching Layer	Anthropogenic Chemicals Detected	Comments
Los Alamos Canyon	H-19 2000 7172	450	22	Porous, well-bedded and well-sorted fall deposits of the Guaje Pumice Bed	Tschicoma Fm. lava flow top	Not sampled	Saturation in this zone was noted while drilling to reach the regional aquifer (Griggs, 1964). The perched zone was not screened, and the regional well was later abandoned.
Los Alamos Canyon	LAOI(A)1.1 323 6833	289	27	Porous, well-bedded and well-sorted fall deposits of the Guaje Pumice Bed	Top of Puye Formation; possible clay-rich soil horizon – see description for well LADP-3	None	A single-screen well was installed in this zone.
Los Alamos Canyon	R-7 1097 6779	373	9	Puye Fm. silty, clayey, and sandy gravels	Clay-rich gravels from 382 to 397 ft deep in the Puye Formation	None	A canyon-floor well was installed with three isolated screens (Stone et al., 2002). Screen #1 in well R-7 is completed in this perched zone.
Los Alamos Canyon	R-7 1097 6779	744	~23	Puye Fm. sandy gravel with abundant pumice clasts	Puye Fm.; possible perching layer from 767 to 772 ft in silty pebble gravel or from 772 to 777 ft in clayey pumiceous sands.	None	Screen #2 in well R-7 is completed in this zone. Geophysical logs and borehole videos suggest additional perched groundwater zones were encountered when the R-7 borehole was drilled.
Los Alamos Canyon	LADP-3 349 6756	320	9	Porous, well-bedded and well-sorted fall deposits of the Guaje Pumice Bed	Smectite- and kaolinite-rich soil a few inches thick at top of Puye Formation	Tritium	Soil development occurs at top of the Puye Formation in outcrops and in boreholes elsewhere. A single-screen well was installed in this zone. (Broxton et al., 1995).

Table 2-B-1.
Characteristics of Deep Perched Groundwater Zones Encountered in Wells on the Pajarito Plateau (continued)

Watershed	Well Name, Borehole Depth (ft), Surface Elev. (ft)	Depth to Water (ft)	Saturated Thickness (ft)	Groundwater Host Rock	Nature of Perching Layer	Anthropogenic Chemicals Detected	Comments
Los Alamos Canyon	LAOI-3.2a 165.5 ~6620	134	>31	Basal ash-flow tuffs of the Otowi Member and porous, well-bedded and well-sorted fall deposits of the Guaje Pumice Bed	The perched zone was not fully penetrated during drilling; perching lithology not known	Nitrate, perchlorate, chloride	Perched groundwater was detected while coring through the lowermost part of the Bandelier Tuff. The bottom of saturation was not penetrated by the borehole. A single-screen well was installed in this zone.
Los Alamos Canyon	Otowi 4 2806 6639	~253	Not known	Puye Fm. gravels	Within Puye Fm. fanglomerate; perching lithology not known	Not sampled	Saturation in this zone was noted while drilling to install a municipal supply well in the regional aquifer (Stoker et al. (1992). The geologic log notes: “Some perched water was visible in a video log of the 48-in hole at about 253 ft where water cascaded in from a large gravel.” This perched zone is not accessed by a well screen in Otowi 4.
Los Alamos Canyon	R-6i 660 ~6995	592	23	Puye Fm. gravels	Poorly sorted fanglomerate with a silty matrix	Nitrate and perchlorate	This zone occurs at the same elevation and may be related to the perched zone identified by borehole video in nearby supply well Otowi 4 during drilling. A single-screen well was installed in this zone.

Table 2-B-1.
Characteristics of Deep Perched Groundwater Zones Encountered in Wells on the Pajarito Plateau (continued)

Watershed	Well Name, Borehole Depth (ft), Surface Elev. (ft)	Depth to Water (ft)	Saturated Thickness (ft)	Groundwater Host Rock	Nature of Perching Layer	Anthropogenic Chemicals Detected	Comments
Los Alamos Canyon	R-9i 322 6383 and LAWS-01 281.5 6305	137	45-99	Cerros del Rio basalt interflow breccia and highly fractured basalt	Massive basalt with few fractures	Tritium	Groundwater was first encountered at a depth of 180 ft, but the water level quickly rose to 137 ft, indicating possible confinement. At R-9i a canyon-floor well was installed with two isolated screens (Broxton et al., 2001a,b). Screen #1 of R-9i is complete in this zone. In LAWS-01, this zone is sampled via a flexible liner with sampling ports (Stone and Newell, 2002).
Los Alamos Canyon	R-9i 322 6383 and LAWS-01 281.5 6305	275	7	Cerros del Rio basalt brecciated flow base	Clay-rich, stratified, basaltic tephra (maar deposits) from 282 to 289.8 ft	Tritium	Water first encountered at 275 ft. The water level stabilized at 264 ft and may be confined (Broxton et al., 2001a,b). Screen #2 in well R-9i is complete in this zone. In LAWS-01, this zone is sampled via a flexible liner with sampling ports (Stone and Newell, 2002).
Los Alamos Canyon	R-9 771 6383	524	48 to 103	Puye Formation sands and gravels	Clay-rich tuffaceous sands and gravels	Tritium	Three stringers of sands and gravels at 579-580.5 ft, 615 ft, and 624-626.8 ft produced perched groundwater (Broxton et al., 2001a). These occurrences probably constitute a single saturated zone because when isolated each yielded the same

Table 2-B-1.
Characteristics of Deep Perched Groundwater Zones Encountered in Wells on the Pajarito Plateau (continued)

Watershed	Well Name, Borehole Depth (ft), Surface Elev. (ft)	Depth to Water (ft)	Saturated Thickness (ft)	Groundwater Host Rock	Nature of Perching Layer	Anthropogenic Chemicals Detected	Comments
							depth-to-water of 524 ft. The water-bearing stringers are enclosed by clay-rich tuffaceous sands and gravels that may be confining units or may simply be unproductive. No well screens were installed in this saturated zone.
Sandia Canyon	PM-1 2501 6513	450	Not Known	Cerros del Rio basalt	Not known	Not sampled	During installation of supply well PM-1, the geologic log notes that water was present in brecciated Cerros del Rio basalt at a depth of 450 ft (Cooper et al., 1965). No other information was given about this zone.
Sandia Canyon	R-12 886 6500	424	76-95	Fractured Cerros del Rio basalt and underlying fluvial sands and silts, and riverine gravels of the lacustrine facies of the Puye Fm.	Clay-rich lake beds of the lacustrine facies of the Puye Fm. from 519-535 ft	Tritium, nitrate	This is probably the same perched groundwater as that encountered in PM-1. Groundwater was first encountered at a depth of 443 ft, but the water level quickly rose to 424 ft before stabilizing, indicating possible confinement. A well was installed with three isolated screens (Broxton et al., 2001c). Screens #1 and #2 are complete in this perched zone.

Table 2-B-1.
Characteristics of Deep Perched Groundwater Zones Encountered in Wells on the Pajarito Plateau (continued)

Watershed	Well Name, Borehole Depth (ft), Surface Elev. (ft)	Depth to Water (ft)	Saturated Thickness (ft)	Groundwater Host Rock	Nature of Perching Layer	Anthropogenic Chemicals Detected	Comments
Mortandad Canyon	I-8 745	675, water level is at top of well sump	Saturated thickness is unknown, but the zone is probably very thin	Fractured Cerros del Rio basalt	Nature of confining bed is unknown	None	A small amount of water was observed trickling from a fracture at 669 ft bgs in the borehole video. A single-screen well was installed, but only a small amount of water has accumulated in the well sump.
Mortandad Canyon	MCOBT-4.4 767 6836	520	2-4 currently	Puye Fm. pebble gravel and silty sands	Top of Cerros del Rio basalt	Tritium, nitrate, perchlorate	Initial depth-to-water was 493 ft, but it has since declined to 520 ft. A single-screen well was installed in this zone (Broxton et al., 2002a).
Mortandad Canyon	I-4 540	520	2-4	Puye Fm. pebble gravel and silty sands	Top of Cerros del Rio basalt	Tritium, nitrate, perchlorate	A single-screen well was installed in this zone. This well was installed as a possible replacement well for MCOBT-4.4.
Mortandad Canyon	R-15 1107 6820	646	~99 (?)	Fractured Cerros del Rio basalt	Clay-rich flow-base rubble or underlying silty basaltic sand (745-746.7 ft)	Tritium, nitrate, perchlorate	Saturation in this zone was noted while drilling to reach the regional aquifer (Longmire et al., 2001). Saturation was first encountered at a depth 646 ft, but a zone of increased water production was noted by the driller from 707-717 ft. It is uncertain whether this occurrence represents one zone or multiple, stacked zones.

Table 2-B-1.
Characteristics of Deep Perched Groundwater Zones Encountered in Wells on the Pajarito Plateau (continued)

Watershed	Well Name, Borehole Depth (ft), Surface Elev. (ft)	Depth to Water (ft)	Saturated Thickness (ft)	Groundwater Host Rock	Nature of Perching Layer	Anthropogenic Chemicals Detected	Comments
Mortan-dad Canyon	I-5 717 6820	687	20	Interflow breccia in Cerros del Rio basalt	Possible confining unit in massive basalt in lower part of Cerros del Rio basalt	Tritium, nitrate, perchlorate	This well was installed adjacent to R-15 and targeted the water production zone from 707 to 717 ft that was noted in that borehole. A single-screen well was installed in this zone. It is uncertain whether the perched zone was fully penetrated by the borehole.
Mortan-dad Canyon	I-6 722 6811	662	43	Interflow breccia and fractured basalt in Cerros del Rio basalt	Possible confining unit in massive basalt in lower part of Cerros del Rio basalt	Tritium, nitrate, perchlorate	This well is 150 ft north of R-15 and I-5, near the Mortandad Canyon stream channel. A single completion well was installed in this zone. The elevation of the SWL is 16 ft higher than at I-5. It is uncertain whether the perched zone was fully penetrated by the borehole.
Pajarito Canyon	R-23 935 6528	Not known	Not known	Cerros del Rio basalt	Not known	Not sampled	Perched groundwater was probably encountered while drilling R-23 to the regional aquifer. Water accumulated in the annulus between the drill casing and the borehole wall above a clay-rich bridge. The accumulated water is probably from a perched zone within the Cerros del Rio basalt. The perched zone was not screened.

Table 2-B-1.
Characteristics of Deep Perched Groundwater Zones Encountered in Wells on the Pajarito Plateau (continued)

Watershed	Well Name, Borehole Depth (ft), Surface Elev. (ft)	Depth to Water (ft)	Saturated Thickness (ft)	Groundwater Host Rock	Nature of Perching Layer	Anthropogenic Chemicals Detected	Comments
Pajarito Canyon	R-19 1902.5 7066	894	18	Puye Fm. sand and gravel beds	Puye Fm. low-porosity sedimentary deposits.	None	R-19 was installed on the mesa south of Threemile Canyon. A perched zone was encountered in Puye Formation fanglomerate overlying Cerros del Rio basalt. Borehole geophysical logs indicate the perched zone is made up of high-porosity sediments overlying low-porosity sediments. A well was installed with seven isolated screens at this site (Broxton et al., 2001d). Screen #2 is complete in this perched zone.
Cañon de Valle	R-25 1942 7516	723	~409	Otowi ash-flow tuff, Guaje Pumice bed, and Puye Fm. fanglomerate	Confining layer occurs in Puye Fm. sedimentary deposits. From 1132 to 1137 ft, cuttings of fine-grained sand and silt are interbedded with gravels and cobbles. Alternating wet and dry sediments occur below this zone to a depth of 1286 ft.	High-explosive compounds and their degradation products, trichloroethene, tetrachloro-ethene	This large saturated zone is separated from the regional aquifer (depth at 1286 ft) by 154 ft of alternating wet and dry fanglomerate deposits. This upper saturated zone is currently interpreted as a perched zone with a leaky confining layer. The top of the same upper saturated zone was penetrated in nearby well CDV-16-1(i) which is located in adjacent Cañon de Valle. A multi-screen mesa-top well was installed at R-25 (Broxton et al., 2002b). Four screens are complete in this thick perched zone.

Table 2-B-1.
Characteristics of Deep Perched Groundwater Zones Encountered in Wells on the Pajarito Plateau (continued)

Watershed	Well Name, Borehole Depth (ft), Surface Elev. (ft)	Depth to Water (ft)	Saturated Thickness (ft)	Groundwater Host Rock	Nature of Perching Layer	Anthropogenic Chemicals Detected	Comments
Cañon de Valle	CDV-16-1(i) 683 7382	563	>120 ft; not fully penetrated	Otowi ash-flow tuff	Perching horizon not known; below drill hole depth	High-explosive compounds	Because of the proximity of CDV-16-1(i) and R-25 (~375 ft), the upper saturated zone in these wells is probably laterally connected. The top of the upper saturated zone is 28 ft higher in CDV-16-1(i) (elev. 6821 ft) compared with R-25 (elev. 6793 ft). A single-screen well was installed in this zone.
Cañon de Valle	CDV-16-2(i) 1063.1 7467	827 (?)	Not known	Puye Fm. fanglomerate	Within Puye Fm. fanglomerate; perching lithology not known	High-explosive compounds	The nature of this perched zone is currently under investigation. Borehole video logs, water level measurements, and the presence of high explosives in groundwater samples indicate that perched water is present. However, efforts to install a well in this zone(s) have not been successful.
Cañon de Valle	R-26 1490.5 7642	173	Zones of thin, dis-continuous saturation associated with fractures	Fractured densely-welded tuff in unit Qbt 3t of the Tshirege Member	Water production associated with fractures	Analyses pending	A piezometer was installed in a borehole adjaent to well R-26 to monitor water levels in this perched zone. The piezometer is screened from 175 to 185 ft deep, and the depth to water is 173 ft. Saturation appears to be associated with low-angle platy fractures in the ash-flow tuff.

Table 2-B-1.
Characteristics of Deep Perched Groundwater Zones Encountered in Wells on the Pajarito Plateau (continued)

Watershed	Well Name, Borehole Depth (ft), Surface Elev. (ft)	Depth to Water (ft)	Saturated Thickness (ft)	Groundwater Host Rock	Nature of Perching Layer	Anthropogenic Chemicals Detected	Comments
Cañon de Valle	R-26 1490.5 7642	About 604	See comments	Cerro Toledo interval	See comments	Analyses pending	R-26 was recently drilled and interpretation of perched water in this zone is preliminary. Borehole geophysical logs suggest high moisture contents below 575 ft to the top of regional saturation at 954 ft. Perched water appears most likely at depths of 580 to 662 ft and 780 to 827 ft. A water level at 604 ft depth was measured during drilling while the borehole was at a depth of 720 ft. Well R-26 was completed with two isolated well screens with the upper screen placed within the perched zone and the lower screen in the regional zone of saturation.
Water Canyon	SHB-3 860 7608	663	> 197 ft (?), probably not fully penetrated	Otowi ash-flow tuff, Guaje Pumice bed, and Puye Fm. fanglomerate	Confining layer probably not penetrated	None	Saturation occurs in the lower Bandelier Tuff and upper Puye Formation. A temporary mesa-top well was installed in the perched zone (Gardner et al., 1993).

In Pueblo Canyon perched water was identified in four wells. At wells TW-2a and R-5, perched water occurs within fanglomerate of the Puye Formation and has a saturated thickness of >7 and about 11.3 m (>23 and about 37 ft), respectively. Depth to water is 33.5 m (110 ft) at TW-2a and about 115.8 m (380 ft) at R-5. These perched zones probably represent relatively small, unrelated water bodies because of their distance from one another (4 km [2.5 mi]), the lateral heterogeneity of Puye Formation deposits, and their varying depths beneath the canyon floor. Wells TW-1a and POI-4 encountered perched water at depths of 36 to 48.8 m (118 to 160 ft), respectively, in Cerros del Rio basalt. The saturated thickness is about 11 m (37 ft) at TW-1a and 6.4 m (>21 ft) at POI-4. Saturation is associated with interflow breccia and sediments in TW-1a and with fractured basalt at POI-4.

In Sandia and Mortandad Canyons perched water was found in Cerros del Rio basalt and the Puye Formation. The water quality of these perched zones includes a component of treated waste-water effluent released to the canyons via outfalls (Longmire et al., 2001; Longmire, 2002; Broxton et al., 2002b). Depth to water is also similar, ranging from 129 to 152 m (424 to 500 ft) in Sandia Canyon and 150 to 197 m (493 to 646 ft) in Mortandad Canyon.

In Sandia Canyon, well R-12 encountered perched water from depths of 135 to 158 m (443 to 519 ft). Saturation occurs in the lower part of the Cerros del Rio basalt and extends downward into underlying lacustrine facies of the Puye Formation (Broxton et al., 2001a). The perched water in this zone may be confined because the borehole was dry until a depth of 135 m (443 ft) was reached, but the water level rose to a depth of 129 m (424 ft) once saturation was encountered. The apparent confining layer at the top of this zone is a massive basalt flow with few fractures. An alternative explanation for the observed rise in water level is that the groundwater is unconfined, but water-bearing interconnected fracture systems were not intersected by the borehole until a depth of 135 m (443 ft). The perching layer consists of clay- and silt-rich lacustrine deposits 5 m (16.5 ft) thick. The saturated thickness of this groundwater body is at least 23 m (75 ft), making it one of the thickest perched groundwater bodies identified in the eastern part of the Pajarito Plateau.

In Mortandad Canyon perched water was encountered in three boreholes. At well MCOBT-4.4, the top of perched groundwater zone occurs at a depth of about 150 m (493 ft), within pebble gravel made up of dacitic volcanic detritus in the Puye Formation. The saturated thickness of this zone is between 3 and 6 m (10 and 30 ft). The perching layer includes one or more of the following lithologies: 1) silty sands and gravels in the lower part the Puye sequence (153.3 to 157.6 m [503 to 517 ft]), 2) clay-rich brecciated rubble at the top of Cerros del Rio basalt (157.6 to 159.3 m [517 to 522.5 ft]), or 3) the massive, unfractured interior of the uppermost Cerros del Rio flow (approximately 159.3 to 163.1 m [522.5 ft to 535 ft]). At wells R-15 and I-5, located 347 m (1140 ft) down canyon of MCOBT-4.4, perched water occurs within the lower part of a thick sequence of Cerros del Rio basalts. The depth to water is 197 m (646 ft) in R-15 and 209 m (686 ft) in the adjacent well I-5 which is offset 20 m (66 ft). Saturation in both wells occurs in fractured lava flows and interflow breccias. The variable elevations of the top of perched saturation and varied saturated thicknesses of 30 m (99 ft) in R-15 and 8+ m (26+ ft) in I-5 illustrate the hetergeneous nature of perched bodies located within basaltic rocks. In R-15, the perching horizon is clay-rich flow-base rubble or underlying silty basaltic sands; the perched water at I-5 was not fully penetrated. Because of their different geologic settings, the perched

groundwater at MCOBT-4.4 and R-15/I-5 probably represent unrelated groundwater bodies of limited lateral extent. Other deep boreholes in Mortandad Canyon did not encounter perched groundwater. Based on the distribution of available boreholes, the lateral extent of individual perched groundwater bodies is probably less than 460 m (1500 ft).

Both perched water occurrences in Mortandad Canyon contain elevated tritium, nitrate, and perchlorate. The highest contaminant levels occur in MCOBT-4.4, which contains 14,750 pCi/L tritium, 12.5 mg/L nitrate plus nitrite (as N), and 179 ppb perchlorate (Longmire, 2002, personal communication). Since 1963, these contaminants were released to the canyon as liquid effluent by a waste treatment facility in the upper part of the canyon. The presence of contaminants in perched groundwater beneath Mortandad Canyon indicates that vertical transport through the vadose zone occurs on the timescale of decades.

A large area of complex perched groundwater occurrences is found in the region bounded by Cañon de Valle on the north and Water Canyon on the south in the southwest part of LANL. Five deep boreholes encountered significant zones of groundwater over a 2.6 km^2 (1 mi^2) area located just east of the Pajarito fault zone. These boreholes included R-25, R-26, CdV-16-1(i), CdV-16-2(i), and SHB-3. Depth to water in these perched zones range from about 183 m (600 ft) just east of the Pajarito fault to about 244 m (800 ft) 2.3 km (1.4 mi) farther east of the fault. Only wells R-25 and R-26 fully penetrate the perched water zones.

At R-26, a water-level measurement of 184 m (604 ft) was obtained when the borehole was 219 m (720 ft) deep. The borehole was eventually completed to a total depth of 454.3 m (1490.5 ft) with the regional water table occurring at a depth of approximately 291 m (954 ft). Borehole neutron, magnetic resonance, and induction logs indicate that high moisture contents occur in rocks below 175 m (575 ft), with perched water most likely at depths of 177 to 202 m (580 to 662 ft) and 238 to 252 m (780 to 827 ft). These perched zones occur within stratified volcaniclastic sediments of the Cerro Toledo interval. Low-permeability sediments within the Cerro Toledo interval probably provide the perching horizons.

R-25, located 1524 m (5000 ft) east of R-26, has two distinct zones of saturation separated by 47 m (154 ft) of partially saturated rocks. The upper zone, which is interpreted as a perched zone, occurs between depths of about 217 to 345 m (711 to 1132 ft) within the Otowi Member and in the upper part of the Puye Formation. An interval of partial saturation occurs below the perched zone from 345 to 392 m (1132 to 1286 ft) depth. Partial saturation was defined by casing off the perched zone and drilling through alternating zones of dry and wet rocks by coring and air-rotary methods. From 392 m (1286 ft) to the total depth of 592 m (1942 ft), continuous saturation representing regional groundwater was encountered within Puye deposits. R-25 was constructed with 9 screens separated by packers using a Westbay™ sampling system. Hydraulic head measurements in isolated screens decrease with depth, indicating downward vertical gradients. Isotopic and water quality data suggest the upper and lower zones of saturation at R-25 represent separate groundwater systems (Longmire, 2003, personal communication).

Table 3-A-1.
Guaje Canyon Watershed Description

Hydrogeologic Element	Characteristic	Description
Surface Water	Flow	Guaje Canyon heads in the Sierra de los Valles on Forest Service land, enters San Ildefonso Pueblo land, and continues to its confluence with lower Los Alamos Canyon approximately a mile west of the Rio Grande (Figure 3-A-1, Figure 3-A-2). Guaje Canyon is part of the Los Alamos Canyon watershed, but is covered separately because it is a large drainage that is largely unaffected by LANL activities. Guaje Canyon contains an interrupted stream with a perennial reach extending from springs located upstream of Guaje Reservoir to some distance downstream of the reservoir. An intermittent reach extends farther downstream to the confluence with lower Los Alamos Canyon. Snowmelt runoff does not reach the Rio Grande. Rendija Canyon heads on the flanks of the Sierra de los Valles and contains an ephemeral stream. Barrancas Canyon heads on the Pajarito Plateau and has intermittent and ephemeral flow.
	Quality	There are no known water quality effects of LANL activities.
Springs	Name	No springs have been found in any of these canyons.
	Quality	See above.
Alluvial Groundwater	Extent	Little or no alluvial groundwater is present in these canyons. Only two alluvial wells have been installed in Guaje Canyon to investigate the presence of alluvial groundwater. These wells were completed in the perennial reach of the canyon and alluvial groundwater was encountered near the stream level. For Rendija Canyon and Barrancas Canyon, no alluvial wells have been installed and no alluvial groundwater is known to exist.
	Depth/Thickness	See above.
	Quality	No impacts of LANL activities on this water are known.
Intermediate Groundwater	Extent/Hydrology	No intermediate groundwater wells have been installed and no groundwater is known to occur in these canyons. Drilling of the water supply wells in Rendija Canyon and Guaje Canyon did not find any intermediate groundwater.
	Depth/Thickness	See above.
	Quality	No LANL liquid discharges have occurred.

Table 3-A-1.
Guaje Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Description
Regional Aquifer	Depth/Hydrology	The regional aquifer occurs in the Puye Formation and the Santa Fe Group in the vicinity of Guaje Canyon. The regional aquifer probably includes rocks of the Tschicoma Formation in the western part of the canyon. The regional aquifer supplies water to the supply wells of the Guaje wellfield. Groundwater flow in the regional aquifer is from the northwest, so no Laboratory contaminant sources are located upgradient of Guaje Canyon sites. The aquifer lies at depths of about 230 to 570 ft in the Guaje wellfield.
	Quality	The water is of generally good quality except for high levels of naturally occurring arsenic—up to 40 µg/L in older, now-abandoned wells. The EPA MCL for arsenic is 10 µg/L.
Contaminants	Potential Sources	These canyons are located north of the Laboratory, mainly on Forest Service land and on San Ildefonso Pueblo. The primary Laboratory activities in the canyons have involved water supply: the Guaje reservoir is no longer in use, and the Guaje wellfield (now operated by Los Alamos County) currently includes five water supply wells. The wells in this field also extend to lower Rendija Canyon. Rendija Canyon contained a small-arms firing range and several sites used as mortar impact areas. Past Laboratory activities are described in more detail in an RFI Work Plan for the North Canyons and an RFI Work Plan for OU 1071.

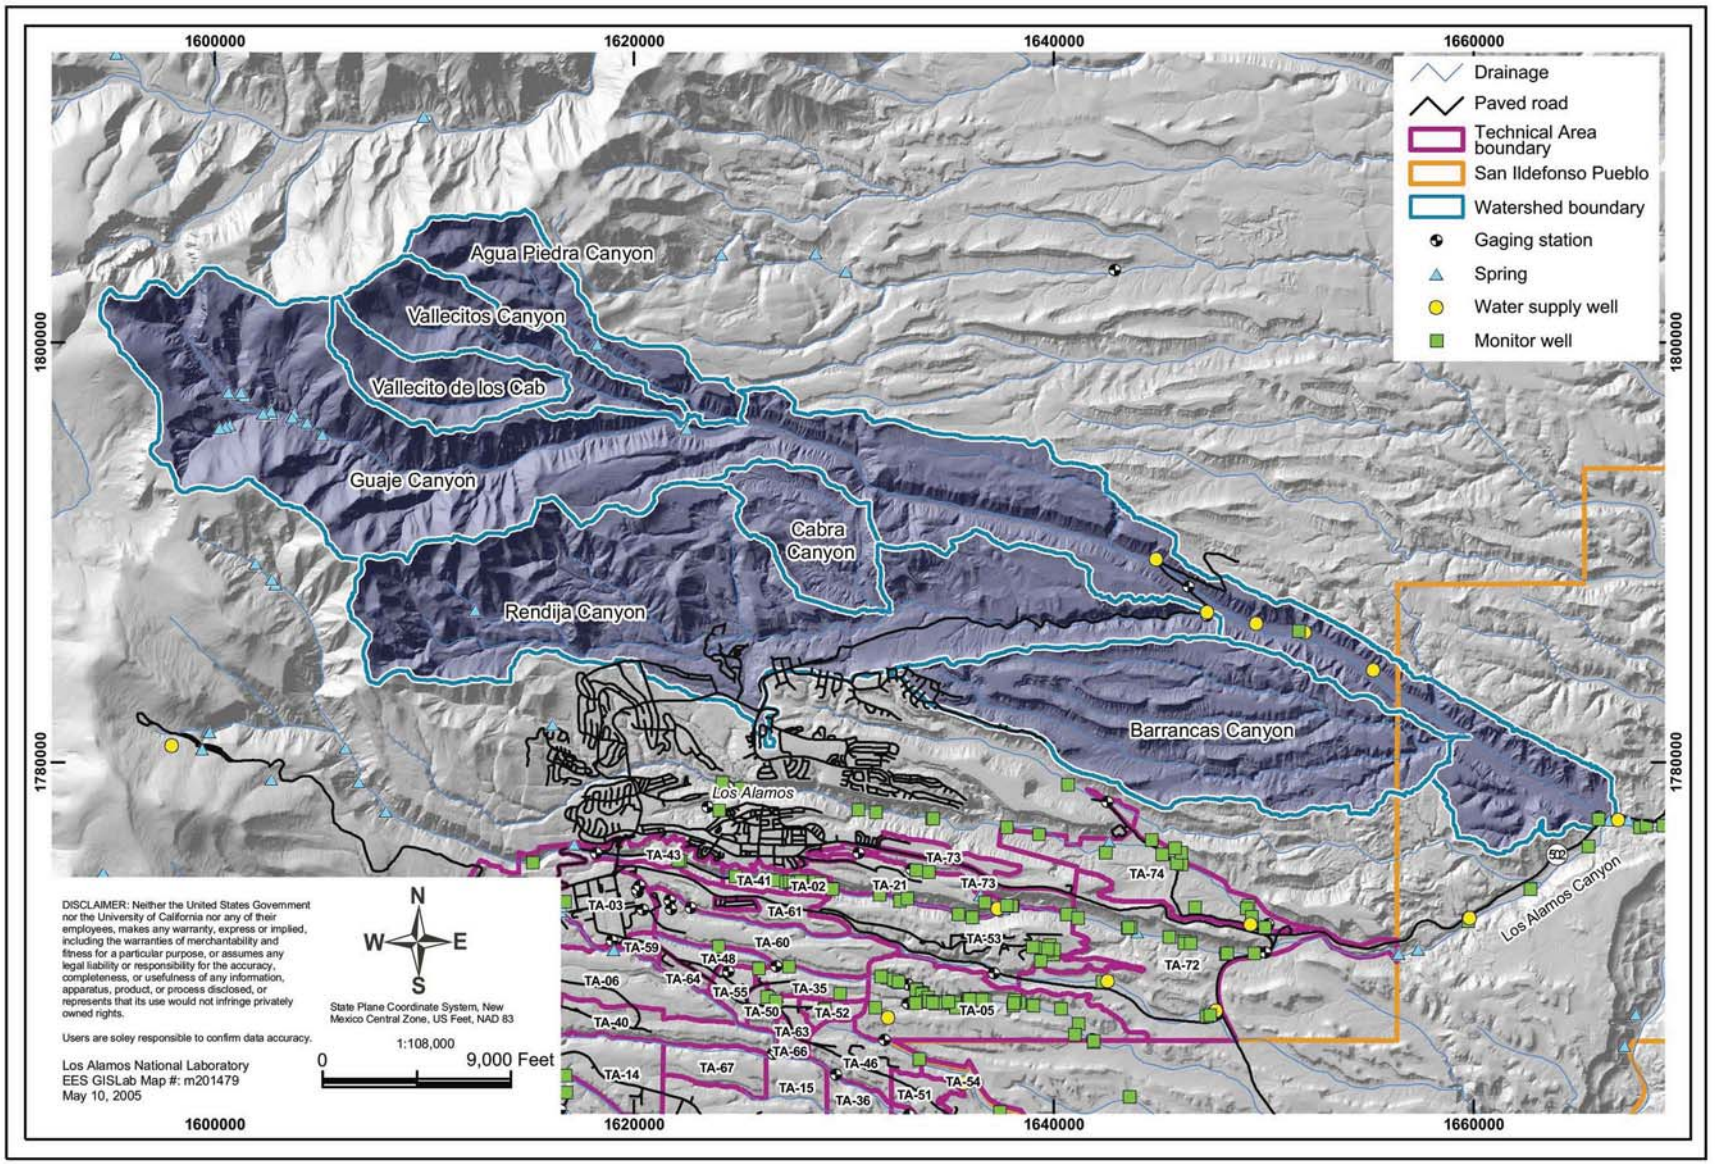

Figure 3-A-2. Guaje Canyon watershed.

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
Surface Water	Flow	Bayo Canyon heads on the Pajarito Plateau on land owned by Los Alamos County and extends across the northeast portion of the Laboratory (TA-74), crosses San Ildefonso Pueblo land to the east, and terminates at its confluence with lower Los Alamos Canyon near Totavi (Figure 3-A-1, Figure 3-A-3). The drainage area of Bayo Canyon is about 4 square miles. Surface water flow in Bayo Canyon is ephemeral and intermittent and there are no springs in the vicinity. Stream losses caused by infiltration into the underlying alluvium and evapotranspiration typically prevent surface flow from reaching Los Alamos Canyon. No alluvial or intermediate groundwater was encountered during drilling of about 90 boreholes at the TA-10 site in upper Bayo Canyon. Drilling at TA-10 has not found	Pueblo Canyon heads on USFS land, crosses Los Alamos County land, then Laboratory land where it joins Los Alamos Canyon just upstream of the San Ildefonso Pueblo boundary (Figure 3-A-1; Figure 3-A-3). The draingage area of Pueblo Canyon is about 6.5 square miles, including Acid Canyon. Surface water in Pueblo Canyon occurs as ephemeral runoff from precipitation and as perennial flow supported by effluent discharge from the Los Alamos County Sewage Treatment Plant. Generally, ephemeral surface water occurs in the upper portion of Pueblo Canyon following summer rains and snowmelt events, and perennial surface water occurs in the lower portion of Pueblo Canyon because of discharges from the Los Alamos County Sewage Treatment Plant. Surface water in Pueblo Canyon rarely flows across the length of the Laboratory. Acid Canyon heads on the Pajarito Plateau in the southwestern portion of the Los Alamos townsite and extends east-northeasterly to its confluence with Pueblo Canyon. The South Fork of Acid Canyon is a short north-trending	Los Alamos Canyon heads on USFS land, crosses Laboratory land, then San Ildefonso Pueblo land before joining the Rio Grande (Figure 3-A-1; Figure 3-A-3). Surface water occurs in Los Alamos Canyon as perennial flow in the upper reaches west of the Los Alamos Reservoir located west of DOE property, and in the lower reaches east of the confluence with Pueblo Canyon. The drainage area of Los Alamos Canyon is about 11.6 square miles, including DP Canyon. Typically, the overflow of water from the reservoir during spring snowmelt results in nearly continuous surface water flow between the western Laboratory boundary and the vicinity of TA-2 for several weeks to several months each year. For most of the year, the only surface flow in Los Alamos Canyon is in lower Los Alamos Canyon due to discharge from the Los Alamos County Sewage Treatment Plant and flow from Basalt and Los Alamos Springs east of the Laboratory boundary. Surface water in Los Alamos Canyon rarely flows across the length of the Laboratory except during snowmelt and summer storm events. Most often, surface waters are depleted by infiltration into canyon alluvium creating saturated zones of seasonally variable extent. DP Canyon heads on the Pajarito Plateau in the southeastern portion of the Los Alamos townsite and extends east-southeasterly to its confluence with Los Alamos Canyon. DP Canyon is located entirely within DOE-owned land except for a short segment at the head of the canyon on land owned by Los Alamos County. Surface flow in DP Canyon is generated by rainfall and snowmelt events. DP

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
		contamination that extends more than a few feet beneath former release sites. Groundwater in the regional aquifer is as described for Guaje Canyon.	tributary to Acid Canyon. Both of these canyons are entirely within land owned by Los Alamos County. These two canyons drain a surface area that is largely paved and developed.	Spring, located in DP Canyon, discharges continuously except for dry periods, such as during the winter and spring of 1996.
	Quality	TA-10 was used as a firing site from 1943 to 1961, for tests with high explosives and radioactive materials. The site included a radiochemistry laboratory. While in operation, the TA-10 sites in Bayo Canyon were investigated for environmental impacts. The site was decontaminated and decommissioned in 1960. TA-10 was the site of an extensive Formerly Utilized Sites Remedial Action Program investigation in 1976. In the mid-1990s the site was studied under a RFI Work Plan for Operable Unit 1079. RFI activities included shrapnel removal and investigation, remediation, or deferred action for several potential release sites. A second RFI work plan was written in 2001.	Key contaminants in Acid Canyon surface water include metals (arsenic, cadmium, manganese, zinc, and cyanide), PAHs (e.g., benzo-a-pyrene, dibenz-a-h-anthracene), and radionuclides (Pu-239, -240, strontium-90, and uranium-234). The metals COPCs are dominated by naturally occurring constituents, or constituents associated with urban runoff. The PAHs are also believed to be associated with runoff from developed areas with the Los Alamos townsite. The radionuclides were detected in bedrock pools in the South Fork of Acid Canyon and are consistent with contaminants found in sediment within the canyon from historical releases from TA-45. The radionuclide contamination generally does not extend beyond the Acid/Pueblo Canyon confluence in detectable concentrations, with the exception of Pu-239, -240 in unfiltered samples.	Key contaminants in upper Los Alamos Canyon surface water include metals (arsenic, manganese, iron, selenium, and cyanide), pesticides, and plutonium-239, -240. The metals are generally considered naturally occurring, although some minor contribution from historical Laboratory releases is possible. The cyanide detects in upper Los Alamos Canyon are believed to be related to combustion of organic matter during the Cerro Grande fire and may also be related to anti-caking and anti-corrosion agents contained in fire retardant. Pesticides are predominantly related to historical use in the Santa Fe National Forest and to use within the Los Alamos townsite. The plutonium-239 is related to outfalls (likely Hillsides 137 and 138) in former TA-1. The Pu-239 is a COPC only for the unfiltered samples indicating the potential that the sample(s) with detections may have contained suspended sediment. Key contaminants in DP Canyon surface water and springs include metals (arsenic, copper, lead, manganese, zinc, and cyanide), pesticides, and radionuclides (americium-241, and strontium-90). Chloride is also present. The metals are either naturally occurring or likely related to townsite runoff, since none of the PRSs in DP Canyon are known for metals contamination, the exception

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
			Surface water in Pueblo Canyon above the confluence with Acid Canyon also has metals COPCs and PAHs that are considered to have a source in townsite runoff. Surface water in Pueblo Canyon below the confluence with Acid Canyon shows metals COPCs (arsenic, manganese, selenium, and cyanide), and organics COPCs (pesticides and PAHs) that are both likely from townsite, national forest, or Cerro Grande fire sources. Radionuclides include Pu-239, -240, americium-241, and cobalt-60.	being the DP Tank Farm (DPTF, SWMU 21-029) which had lead contamination associated with leaks from the tanks. However, no other of the COPCs from the DPTF are present. The cyanide detections in DP Canyon are from DP Spring and a location at the very head of DP Canyon suggesting a source other than Laboratory operations. The radionuclides are COPCs only for the unfiltered samples indicating the potential that the detections are related to the presence of suspended sediment in the samples. DP Spring consistently shows elevated strontium-90 concentrations related to surface water and alluvial groundwater discharge from Reach DP-2 where strontium-90 is present throughout the sediment due to historical releases from SWMU 21-011(k). Key COPCs in surface water and springs in lower Los Alamos Canyon include metals (antimony, arsenic, beryllium, copper, possibly mercury, molybdenum, nickel, selenium, thallium, and cyanide), PAHs (benzo_k_fluoranthene), and pesticides (DDE_4_4_, and DDP_4_4_), and only strontium-90 from unfiltered surface water. The constituents present in lower Low Alamos Canyon appear to be primarily naturally occurring or related to sources other than Laboratory operations. Of the metals identified as COPCs for lower Los Alamos Canyon, only molybdenum (and mercury?) have known Laboratory sources up canyon. The cyanide is believed to be related to the combustion of organic matter during the Cerro Grande fire. Detections of cyanide in the lower canyon are thought to be related to transport of ash from burn areas in the upper watershed during floods. Strontium-90 could be

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
				from either Los Alamos or Pueblo Canyon, but based on estimated inventories of strontium-90, it is most likely associated with Los Alamos Canyon (specifically SWMU 21-011(k).
Springs	Name	There are no springs in Bayo Canyon.	There are no springs in Acid and Pueblo Canyons,	Discharge at DP Spring is highly variable, generally ranging from dry to less than one gallon per minute, and has been observed to respond rapidly to storm-water runoff from upper DP Canyon. Surface water flow generally extends for less than 50 ft down canyon from the point where spring flow joins the stream channel. Basalt Spring is recharged by water from the County Sewage Treatment Plant in Pueblo Canyon. It has variable estimated discharge rates from 1 to 10 gallons per minute. LA Spring discharges along the south slope of the canyon approximately 300 meters downstream of Basalt Spring.
	Quality	See above.	See above.	Chloride, sodium, and manganese, barium, boron, HE, and solvents at concentrations above background.
Alluvial Groundwater	Extent		Two saturated zones are known to occur in the alluvium of Pueblo Canyon. The first is in the upper reach from the headwaters to approximately the Rendija Canyon Fault. The eastern limit of this saturated zone has not been clearly defined and it may extend further down canyon. The second is in the lower reach downstream of the Los Alamos County Sewage Treatment Plant where saturated conditions are supported year-round due to effluent	Two saturated zones are known to occur in the alluvium of Los Alamos Canyon. The first is in the upper part of Los Alamos Canyon and extends eastward from the Los Alamos Reservoir to the vicinity of observation well LAO-4.5 west of State Rte. 4. The second is in the lower part of Los Alamos Canyon and extends from Basalt Spring to the Rio Grande. Alluvial groundwater in lower Los Alamos Canyon near Basalt and Los Alamos Springs is chemically similar to surface water flow supported by these springs. The chemistry of the water discharging from Basalt Spring is

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
			releases from the sewage treatment plant. The extent of saturation is variable due to fluctuation in runoff and volume of effluent released during the year. The volume of effluent released into the canyon typically decreases during the spring and early summer months as wastewater from the plant is pumped up canyon for irrigation use on the municipal golf course. From 1951 to 1964, surface flow in the mid-reach of Pueblo Canyon was augmented by liquid effluent from the former TA-45 radioactive liquid waste treatment facility via Acid Canyon. In addition, Los Alamos County operated a sewage treatment plant in upper Pueblo Canyon (known as the Pueblo Sewage Treatment Plant) until the current Los Alamos County Sewage Treatment Plant came on-line in 1963. Effluent from these past sources likely supported sustained saturated conditions throughout the mid-reach of Pueblo Canyon as well as shallow bedrock springs such as Hamilton Bend Spring, just west of the current Los Alamos County Sewage Treatment Plant. The sewage treatment plants are sources of boron and nitrate. This	similar to effluent from the Los Alamos County Sewage Treatment Plant. The chemistry of water discharging from Los Alamos Spring may represent an isolated perched system as it does not contain characteristic major ions indicative of sewage effluent. Alluvial groundwater in lower Los Alamos Canyon, from the confluence of Guaje Canyon and Los Alamos Canyon to the Rio Grande, shows chemical similarity to both regional aquifer water and surface water from the Rio Grande (LANL, 2004b, 2002, 2001a).

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
			alluvial groundwater may have provided the source for infiltration to intermediate perched zone groundwater or the regional aquifer. Shallow spring flow (including Hamilton Bend Spring) ended following closure of TA-45 and the Pueblo Sewage Treatment Plant.	
	Depth/ Thickness		See above.	In middle and upper Los Alamos Canyon, the saturated thickness in the alluvium varies seasonally from a few feet in the winter months to 25 ft in the spring and summer months when recharge is the greatest. The alluvial groundwater provides recharge to intermediate perched zones by infiltrating along preferential pathways such as faults or permeable bedrock units.
	Quality		Known contaminants at former TA-45 include nitrate, perchlorate, tritium, isotopes of uranium and plutonium, strontium-90, cesium-137, and gross-alpha radiation. The contaminant histories for nitrate, tritium, and strontium-90 illustrate trends in Pueblo Canyon surface water and groundwater. Nitrate has been present from Laboratory radioactive liquid waste effluents and from Los Alamos County Sewage Treatment Plant sanitary effluent. The highest values were found in surface water in the 1950s and 1960s, possibly related to both types of sources. With decommissioning of the radioactive outfall in 1964 and moving	Alluvial groundwater has been found in DP Canyon at wells LAUZ-1 and LAUZ-2, installed for the ER investigation at TA-21. Strontium-90, tritium, and some organic compounds have been detected at LAUZ-1. Time series plots of nitrate, tritium, plutonium-239, strontium-90, and molybdenum provide a picture of contaminant trends in Los Alamos Canyon groundwater. Nitrate in discharges into DP Canyon from TA-21 caused surface water and alluvial groundwater concentrations to exceed 100 mg/L (nitrate as nitrogen), or 10 times the MCL, until discharges ceased in 1986. Nitrate concentrations have returned to background since discharges ended. TA-21 effluent caused tritium activities in surface water and alluvial groundwater in and downstream of DP Canyon

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
			the sanitary discharge downstream to the Bayo Treatment Plant, less water and less nitrate are present in the upper portion of the drainage in recent years. Tritium and strontium-90 histories characterize the radioactive effluent releases into Acid Canyon. Tritium persisted in surface water and alluvial groundwater at fairly high levels for about a decade after effluent releases ceased, but has dropped to background levels since. The highest measured strontium-90 activity was about 500 pCi/L in Acid Canyon surface water in 1960. With no present source, levels have dropped dramatically and strontium-90 is now seen only at low activities, below 1 pCi/L in alluvial groundwater.	to reach values up to 5,000,000 pCi/L or 250 times the MCL. As with nitrate, tritium activities decreased greatly after discharges ceased. In Los Alamos Canyon above the mouth of DP Canyon, the Omega West Reactor cooling line leaked water containing tritium from 1956 to 1993. As a result of this leak, tritium activity in alluvial groundwater remained at values around 10,000 pCi/L or half of the MCL. Once the leak was shut off, tritium levels in Los Alamos Canyon water returned to background. Strontium-90 contamination in surface water and alluvial groundwater came from reactor sources at TA-2 and effluent discharges from TA-21. The strontium-90 activity in DP Canyon surface water reached 28,600 pCi/L. There is no present source, and activities of this isotope have dropped greatly after discharges ceased. However, strontium-90 persists in alluvial groundwater at levels above the EPA MCL of 8 pCi/L due to the large inventory in alluvial sediment, providing a source to groundwater. Migration of strontium-90 is considered to be controlled by cation exchange. Effects of Manhattan Project releases in upper Los Alamos Canyon cause plutonium-239, -240 activity in alluvial groundwater to remain at about 25% of the DOE 4 mrem drinking water derived concentration guide (DCG) of 1.2 pCi/L. Discharges from TA-21 resulted in plutonium-239, -240 activity in surface water much above the DOE 4 mrem DCG, even exceeding the 100 mrem DCG of 30 pCi/L in the late 1960s. Plutonium activity has decreased substantially with the end of discharges in 1986, but is still

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
				occasionally detected in surface water and alluvial groundwater below the former outfall. A short section of alluvial groundwater in Los Alamos Canyon has molybdenum concentrations near or above the New Mexico groundwater standard of 1,000 µg/L. In the early 1990s, molybdenum concentrations in Los Alamos Canyon alluvial groundwater rose sharply above background and exceeded the New Mexico groundwater limit in 2000. The source of this molybdenum is sodium molybdate, a water-treatment chemical commonly used in cooling towers at TA-53. The Laboratory discontinued use of sodium molybdate in June 2002.
Intermediate Groundwater	Extent/ Hydrology		Intermediate perched zones have been identified in two areas beneath Pueblo Canyon. One zone is in the middle reach of Pueblo Canyon where test well (TW)-2A is completed within fanglomerates of the Puye Formation. The perched zone occurs at a depth of about 120 ft. The second is in lower Pueblo Canyon (wells TW-1A and POI-4) within a thick sequence of Cerros del Rio basalts, at a depth of about 188 ft. This intermediate perched zone may be one source of water contributing to the flow from Basalt Spring in Los Alamos Canyon. Fairly rapid communication from Pueblo Canyon surface water and alluvial groundwater to the intermediate perched groundwater was interpreted	Several intermediate perched zones have been encountered in Los Alamos Canyon between TA-2 and State Road 4. A perched zone was encountered at well R-6i east of the facilities at TA-21 on the mesa top. The zone occurs within the Puye Formation at a depth of 593 ft.

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
			by the USGS based on water level measurements and similarities in water quality.	
	Depth/Thickness		See above.	The upper intermediate perched zone occurs within the Guaje Pumice Bed. This zone was encountered in borehole LADP-3 (at 325 ft). This same zone may have been penetrated by test hole H-19, west of the Los Alamos Canyon Bridge. The saturated thickness of this zone decreases from west to east, ranging from 22-ft at LAOI(A)-1.1 to 5-ft at LADP-3. A deeper intermediate perched zone was encountered in LAOI(A)-1.1 in the Puye Formation at about 317 ft. Another hole was drilled from the mesa top at MDA V in TA-21 which is approximately midway between LAOI(A)-1.1 and LADP-3 to investigate the lateral extent of the Guaje Pumice intermediate perched zone under DP Mesa. The MDA V Deep Hole (borehole 21-2523) did not find saturated conditions in the Guaje Pumice Bed at this location, indicating that this intermediate perched zone does not extend northward under DP Mesa. Other intermediate perched zones have been found in the basalt at R-9 near SR-4 at 180 and 275 ft. This well also found three possible saturated zones between depths of 570 and 626 ft, about 100 ft above the regional aquifer.
	Quality		Analysis of water samples from well TW-2A show that this perched zone contains elevated activities of tritium (2,228 pCi/L). This suggests that tritium associated with the former TA-45 treatment plant has infiltrated the canyon floor and migrated vertically, at	Average activities of tritium were 2.98 pCi/L in the perched zone, within the upper Puye Formation at well R-7 east of well LAOI(A)-1.1. Tritium was initially found in LADP-3 at 5500 pCi/L but activity has declined greatly since then, probably related to cessation of the Omega West Reactor cooling line leak in 1993. Average activities of tritium in the two intermediate perched zones at R-9i were 200 pCi/L at

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
			least to the depth of the intermediate perched zone at TW-2A. The tritium history for TW-2A shows a steep decrease the early 1980s, related to the cessation of discharges into Acid Canyon in 1964. Elsewhere in intermediate perched groundwater, tritium has been detected mainly at trace levels. In core from drilling of well R-2, perchlorate was found in more than 50% of the samples. Nitrate histories show that concentrations in TW-1A have often been up the 10 mg/L MCL. The high nitrate value in this and other wells in 1994 resulted from a sample preservation error. In about 1980, the Los Alamos County Bayo Sanitary Wastewater Treatment Plant, which discharges into Pueblo Canyon upstream of TW-1, greatly increased discharges. This increase in flow and infiltration apparently resulted in the higher concentrations of nitrate and chloride in TW-1 beginning about 1981. Nitrate (as nitrogen) concentrations in TW-2A, upstream of the Bayo treatment plant, have been 3 mg/L or less. Strontium-90 has not been consistently detected in intermediate perched	180 ft and 132 pCi/L at 275 ft during characterization sampling. Activities of tritium were 3802 pCi/L and concentrations of nitrate (as nitrogen) were 4.20 mg/L. Recharge from DP Canyon is most likely the dominant source of water to this perched intermediate zone. Perchlorate has been detected in unsaturated core samples from LADP-3 and R-8. However, perchlorate appears to have a very restricted vertical extent (<15 ft thick) in LA Canyon based on these boreholes. No other perchlorate detections occurred over the 200-350 ft sampling depth in the two boreholes. A similar situation occurs in DP canyon where LAUZ-1 perchlorate is also restricted to a narrow vertical depth range. In this borehole, all but one of the samples were non-detects for perchlorate. Vadose zone cores from DP Mesa boreholes LADP-4 (drilled on a bench above the DP canyon bottom near the former TA-21 radioactive liquid effluent outfall) and borehole 21-2523 (drilled east of MDA V), show a more extensive zone (>200 ft) of perchlorate contamination than occurs in the bottom of Los Alamos or DP canyon. In addition, both of these core holes show co-contamination of chlorate and nitrate. Chlorate has been detected in DP Spring, but chlorate and perchlorate have not been detected in other Los Alamos Canyon surface or groundwater samples.

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
			groundwater.	
Regional Aquifer	Depth/ Hydrology		Depth to the regional aquifer is known in several locations in Pueblo Canyon, including TW-4 in upper Pueblo Canyon, at well TW-2 in the middle reach, and at wells TW-1 and O-1 near the confluence with Los Alamos Canyon. Water level measurements show depths to water to be 1173 ft in 2003 at TW-4, 807 ft in 2001 at TW-2, and 686 ft in 2001 at O-1. Based on Laboratory water-level maps, the general direction of groundwater flow in the regional aquifer is east in the vicinity of Pueblo Canyon. East of the Rendija Canyon Fault, the top of the regional aquifer is within the Totavi Lentil of the Puye Formation.	Depth to the regional aquifer is known in several locations in Los Alamos Canyon; at TW-3 and O-4, at O-1 near the confluence with Pueblo Canyon, and at LA-5 and LA-1B in the lower reach. Water level measurements show depths to water to be 784 ft in 2001 at TW-3, 68 ft in 2001 at O-1, 762 ft in O-4 in 1995, and -18 ft (artesian) in 1996 at LA-1B. Based on Laboratory water-level maps, the general direction of groundwater flow in the regional aquifer is east in the vicinity of Los Alamos Canyon.
	Quality		Contaminants have been detected in the regional aquifer, particularly nitrate in TW-1, indicating that the pathways for contaminant migration may be active at least along the lower portion of the canyon. Tritium has been found in TW-1 at up to 360 pCi/L though recent levels are lower at 140 pCi/L. Perchlorate is found within the regional aquifer in Pueblo Canyon, notably in water supply well O-1 at 2.8 ppb using the LC/MS/MS analytical method. Well O-1	Tritium has been detected in the regional aquifer at up to 80 pCi/L in TW-3 (though recent samples are nondetects) and 24 pCi/L in R-9. In TW-3 nitrate (as nitrogen) values were below 0.3 mg/L prior to 1967, but have averaged above 0.6 mg/L since 1981 with values up to 0.97 mg/L in 1994. Activities of tritium were 181 pCi/L in the regional aquifer at well R-6 during development. Concentrations of nitrate (as nitrogen) were 0.49 mg/L at the well. Concentrations of perchlorate were less than detection (0.0005 ppm) using the ion chromatography method. Because tritium was detected and nitrate concentration is within background, a component of young water containing

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
			also contains a consistent 35-45 pCi/L of tritium and higher nitrate (as nitrogen) than any other regional aquifer well, excluding TW-1. Nitrate (as nitrogen) has been about 1.7 mg/L at well O-1 compared with approximately 0.5 mg/L in other water supply wells. Characterization well R-4, west of the Bayo Canyon and Pueblo Canyon confluence, contained 19.49 pCi/L of tritium and 1.39 ppm of nitrate (as nitrogen). These results indicate that the regional aquifer has experienced recent recharge that is most likely the result of past discharges to Acid Canyon to the west of well R-4.	tritium may have originated from a different source other than TA-21. This assumes that tritium, nitrate, and perchlorate were released to the environment at the same time.
Contaminants	Potential Sources		Contaminant sources affecting Pueblo Canyon include two inactive TAs (TA-1 and TA-45). TA-1 included the portion of the present-day Los Alamos townsite where the majority of the theoretical and technical work was accomplished at the Laboratory from 1943–1954. Acid Canyon was the original disposal site for liquid wastes generated by research on nuclear materials for the World War II Manhattan Engineer District atomic bomb project. From 1943 to 1951, Acid Canyon received untreated radioactive industrial effluent from the TA-1	Several contaminant sources affected upper Los Alamos Canyon. TA-2, located in upper Los Alamos Canyon, was the location of a series of nuclear reactors. The cooling line for the Omega West Reactor leaked water with tritium activity of at least 100,000 pCi/L into the alluvium, probably from 1956 until 1993. TA-21, which is on DP Mesa, north of Los Alamos Canyon, was the site of plutonium processing facilities. The site discharged treated liquid radioactive effluent into DP Canyon from 1952 to 1986 and includes Material Disposal Areas A, B, T, U, and V. TA-41, located in upper Los Alamos Canyon, was used for testing of nuclear weapons components. TA-53, the site of the Los Alamos Neutron Science Center (LANSCE) linear accelerator facility, lies on the mesa south of the canyon.

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
			research activities. The TA-45 treatment plant was completed in 1951 and discharged treated effluents containing residual radionuclides into Acid Canyon from 1951 to 1964. TA-73 is the site of the DOE airport and former landfill, above Pueblo Canyon. Pueblo Canyon also receives sanitary effluent from Los Alamos County Sewage Treatment Plant in Bayo Canyon. The county operated two other sewage treatment plants along Pueblo Canyon in the past. More detailed information about these sites can be found in the Task/Site Work Plan for Operable Unit 1049, Los Alamos Canyon and Pueblo Canyon, and the RFI Work Plans for Operable Units 1078, 1079, 1100, and 1106.	Water from National Pollutant Discharge Elimination System (NPDES) permitted outfalls, sanitary treatment, and reactor beam cooling water ponds flowed to Los Alamos Canyon. TA-1 included the portion of the present-day Los Alamos townsite where the majority of the theoretical and technical work was accomplished at the Laboratory from 1943 to 1954. Several facilities discharged untreated chemical waste streams into the canyon.
	Type		Septic tank outfall located on the south rim of Acid Canyon in the 1940s containing plutonium-239, -240 and PCBs. Former Pueblo Canyon WWTP operated from 1951 until 1991. Sludge from the Pueblo Canyon Sewage Treatment Plant contained metals at levels above background. Former Central Sewage Treatment Plant operated from 1947 until 1961. Metals and organic chemicals, including mercury and DDT, were contaminants	TA-1 Hillsides 137, 138, and 140 received discharges from septic tank outfalls from 1943 until the late 1950s. Radionuclides are the primary contaminants at these hillside sites, although some metals contamination is also present). TA-2 housed a series of research nuclear reactors, including the Omega West Reactor, which was a source of tritium releases into alluvial groundwater. Other SWMUs at TA-2 include leach fields for water boiler reactors. Cesium-137 and strontium-90 are primary contaminants associated with the leach fields, and strontium-90 has historically been detected in alluvial groundwater monitoring wells

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
			identified at the outfalls. Outfalls from former TA-1 and former TA-45. TA-45 was the site of the first radioactive liquid waste treatment facility. TA-1 outfalls into Acid Canyon were not treated. These outfalls were the most significant sources of radionuclide and other contamination in Acid and Pueblo Canyons. Plutonium-239,-240 is the primary contaminant, although other radionuclides, metals, and some organic chemicals are also present.	down canyon of the site. TA-41 was used for weapons development and long-term studies of weapon subsystems. The primary contaminant sources are a septic system and a sewage treatment plant. Initial data from these SWMUs indicate radionuclides at levels above background, but characterization of TA-41 is incomplete. TA-21 was the site of a plutonium processing plant and polonium and tritium research laboratories. Outfalls were the primary source of radionuclide contaminants in DP and upper Los Alamos Canyons. Radionuclides, particularly cesium-137, and strontium-90, are the primary contaminants discharged from this outfall. TA-53 includes a proton accelerator and associated experimental and support buildings used for research with subatomic particles; it is the current site of the Los Alamos Neutron Science Center (LANSCE). The accelerator became fully operational in 1974. Occasional releases occurred from three surface impoundments at the east end of TA-53, referred to as consolidated SWMU 53-002(a)-99, which have contributed contamination to an unnamed tributary drainage to Los Alamos Canyon. The impoundments received sanitary, radioactive, and industrial wastewater from various TA-53 buildings as well as septic tank sludge from other Laboratory buildings. The northern impoundments were active from the early 1970s until 1993. The southern impoundment was active from 1985 until 1998. Inorganic chemicals, organic chemicals, and radionuclide COPCs have been identified at the

Table 3-A-2.
Los Alamos Canyon Watershed Description

Hydrogeologic Element	Characteristic	Bayo Canyon	Acid and Pueblo Canyons	DP and Los Alamos Canyons
				impoundments and in the drainage. SWMU 21-018(a), Material Disposal Area (MDA) V, received liquid waste effluent from laundry operations and includes three absorption beds on the south side of DP Mesa that sometimes overflowed into Los Alamos Canyon. Sediment sampling in 1946 documented that plutonium from this source was entering the main channel in Los Alamos. Additional outfalls that discharged off the south rim of DP Mesa include SWMUs 21-023(c), 21-024(b), 21-024(c), 21-024(i), and 21-027(a). SWMU 21-029, the DP Tank Farm, was a fuel distribution station with aboveground and underground fuel tanks from 1946 to 1985. Diesel range organic (DRO) and gasoline range organic (GRO) hydrocarbon contamination was identified at two areas of bedrock seeps in the DP Canyon channel and observed to periodically form a sheen in surface water adjacent to the site. The MDAs at TA-21 are not considered to be important from the perspective of releases to the canyons.

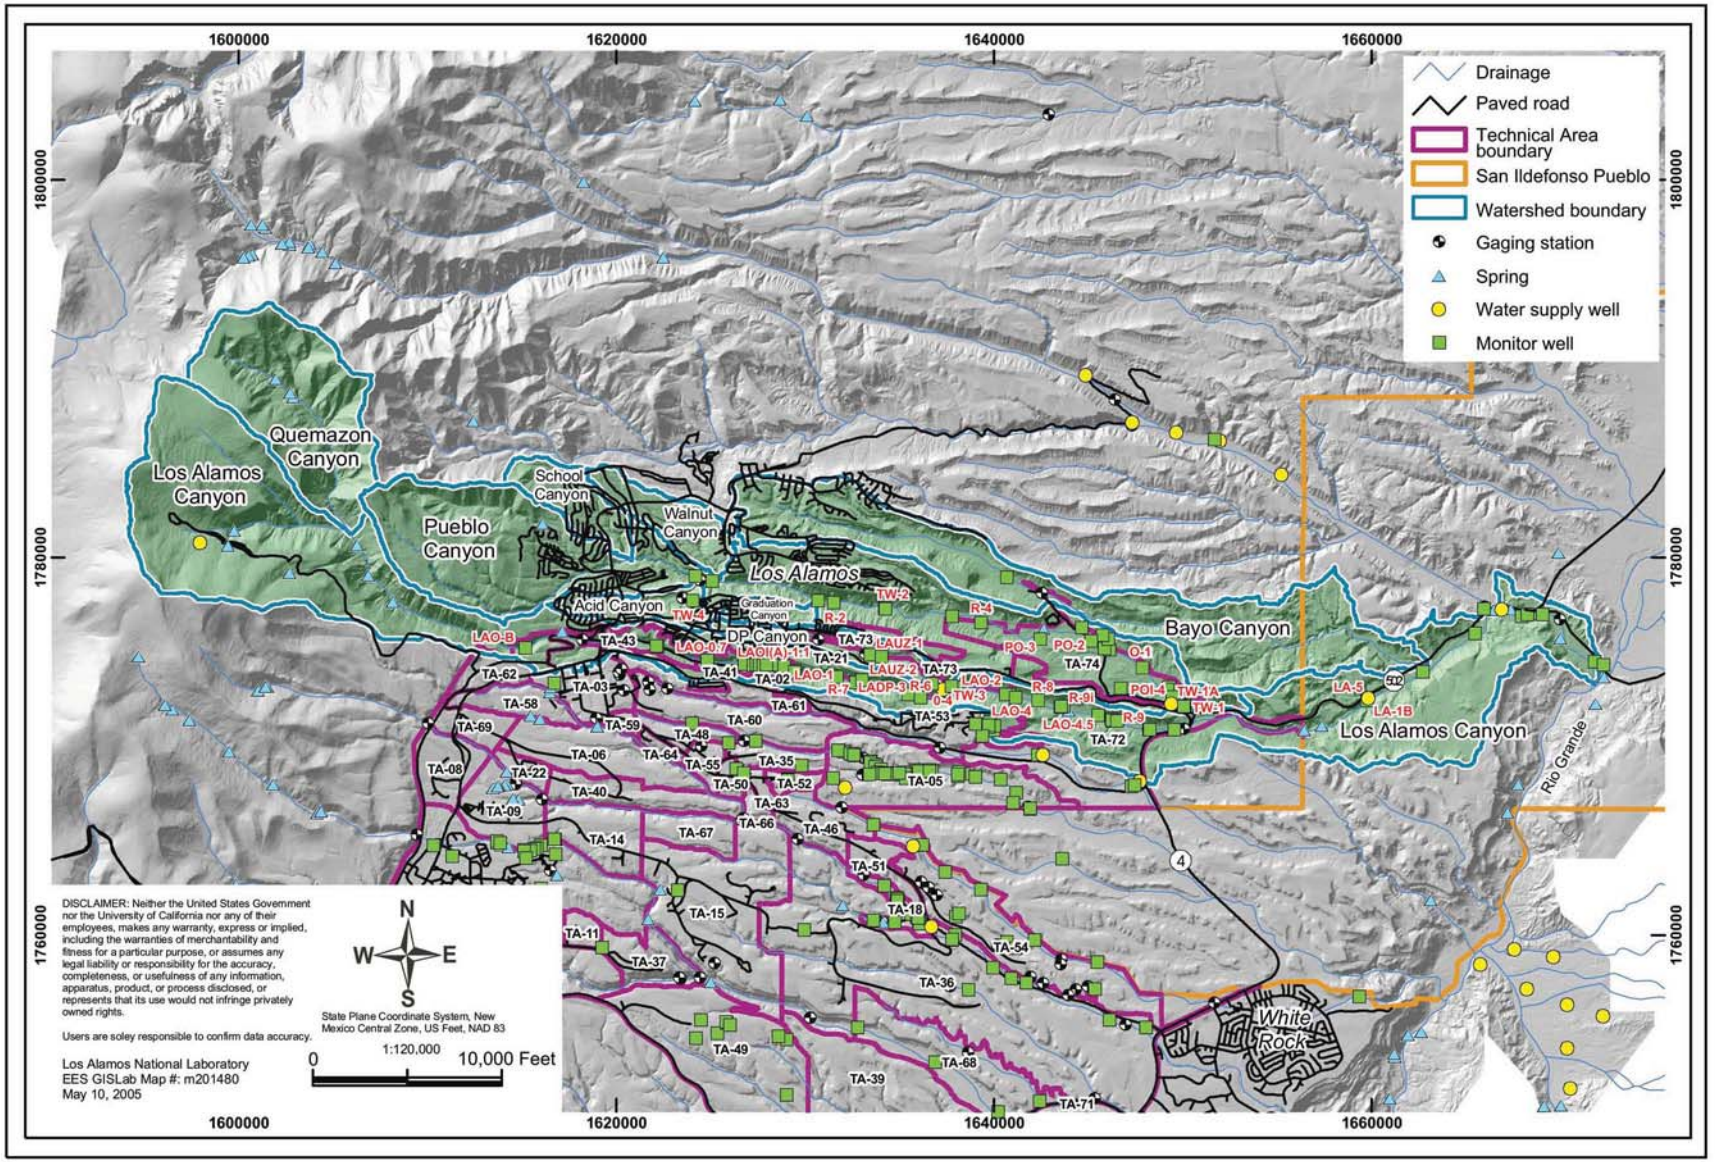

Figure 3-A-3. Los Alamos Canyon watershed, including Los Alamos Canyon, Bayo Canyon, Acid Canyon, Pueblo Canyon, and DP Canyon.

Table 3-A-3.
Sandia Canyon Watershed Description

Hydrogeologic Element	Characteristic	Description
Surface Water	Flow	Sandia Canyon is located on the plateau within the central part of the Laboratory (Figure 3-A-1, Figure 3-A-4). The canyon heads on Laboratory property within TA-3 at an elevation of approximately 7300 ft and trends east-southeast across the Laboratory, Bandelier National Monument, and San Ildefonso Pueblo land, and reaches the Rio Grande in White Rock Canyon at an elevation of 5450 ft. Sandia Canyon has a relatively small total drainage area of about 5.5 mi^2. Surface water occurs in Sandia Canyon as ephemeral runoff from precipitation and as NPDES-permitted effluent discharge from the Laboratory sanitary wastewater sewage treatment plant and the TA-3 power plant. On a volume basis, baseflow in Sandia Canyon represents one of the largest potential non-natural groundwater recharge sources at the Laboratory. The NPDES outfalls support perennial and intermittent flow within the upper 2.5 miles of the canyon, and a wetland has developed because of the artificial flows. The lower 9.5 miles of channel is ephemeral.
	Quality	Surface water quality reflects sewage effluent with nitrate, chloride, and metals slightly above background by approximately 2 to 5 times. Stream sediments contain PCBs and they are detected in surface water at low levels.
Springs	Name	Sandia Spring discharges about 1 gpm approximately 0.5 mile from the Rio Grande.
	Quality	Contaminant levels are at detection or background levels.
Alluvial Groundwater	Extent	Little is known about the occurrence of alluvial groundwater in Sandia Canyon. Most likely, infiltration of surface water creates a saturated zone of seasonally variable extent within the alluvium in the upper reach of the canyon. However, the extent and thickness of alluvial groundwater has not been characterized. Two wells were installed in 1990 to look for alluvial groundwater near the eastern Laboratory boundary as part of the HSWA permit special conditions. Both wells, SCO-1 and SCO-2, were dry at the time of installation. Periodic attempts to sample these wells as part of the Laboratory's annual environmental surveillance activities have found no water in the wells.
	Depth/Thickness	See above.
	Quality	NA

Table 3-A-3.
Sandia Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Description
Intermediate Groundwater	Extent/Hydrology	An intermediate perched zone was found within basalts near SR-4.
	Depth/Thickness	The perched zone is at about 440 ft in well R-12.
	Quality	The perched zone has tritium above background (60 to 160 pCi/L). In the borehole for R-11, nitrate (as nitrogen) was above background, at about 4.9 mg/L of nitrate (as nitrogen) at a depth of 443 ft bgs.
Regional Aquifer	Depth/Hydrology	The regional aquifer lies at about 800 ft depth below Sandia Canyon near SR-4.
	Quality	Tritium in well R-12 is about 45 pCi/L, and is above background. Concentrations of nitrate (as nitrogen) were 0.5 ppm at the regional water table during drilling. Characterization well R-11 west of supply PM-3 contained 12.8 pCi/L of tritium and 4.91 ppm of nitrate (as nitrogen), indicating that this well has experienced recent recharge. The $\delta^{15}N_{air}$ of nitrate values were +0.5 and +0.7% for the sample, which suggests that nitrate has not undergone fractionation, and the two values are very consistent with that of nitrate derived from neutralized nitric acid. The most likely source of this unique nitrate at well R-11 is Mortandad Canyon, which has a long history of discharges containing nitrate derived from neutralized nitric acid.
Contaminants	Potential Sources	Potential Release Sites (PRS) within the watershed are located at TAs-3, -53, -60, -61, -72, and former TA-20. The Laboratory started use of Sandia Canyon lands during the 1940s. The Laboratory's primary use of Sandia Canyon has been for liquid waste disposal from industrial and sanitary systems, particularly the treated effluents from the TA-46 Sewage Treatment Plant and cooling tower blowdown from the TA-3 power plant. Other sources include discharges from the TA-53 accelerator, the protective force small arms live firing range at TA-72, and a small high explosives firing site near TA-3 (former TA-20).
	Type	Nitrate, perchlorate, chromium, copper, PCBs in sediments, HE compounds, tritium, isotopes of uranium and plutonium, lead in surface soils.

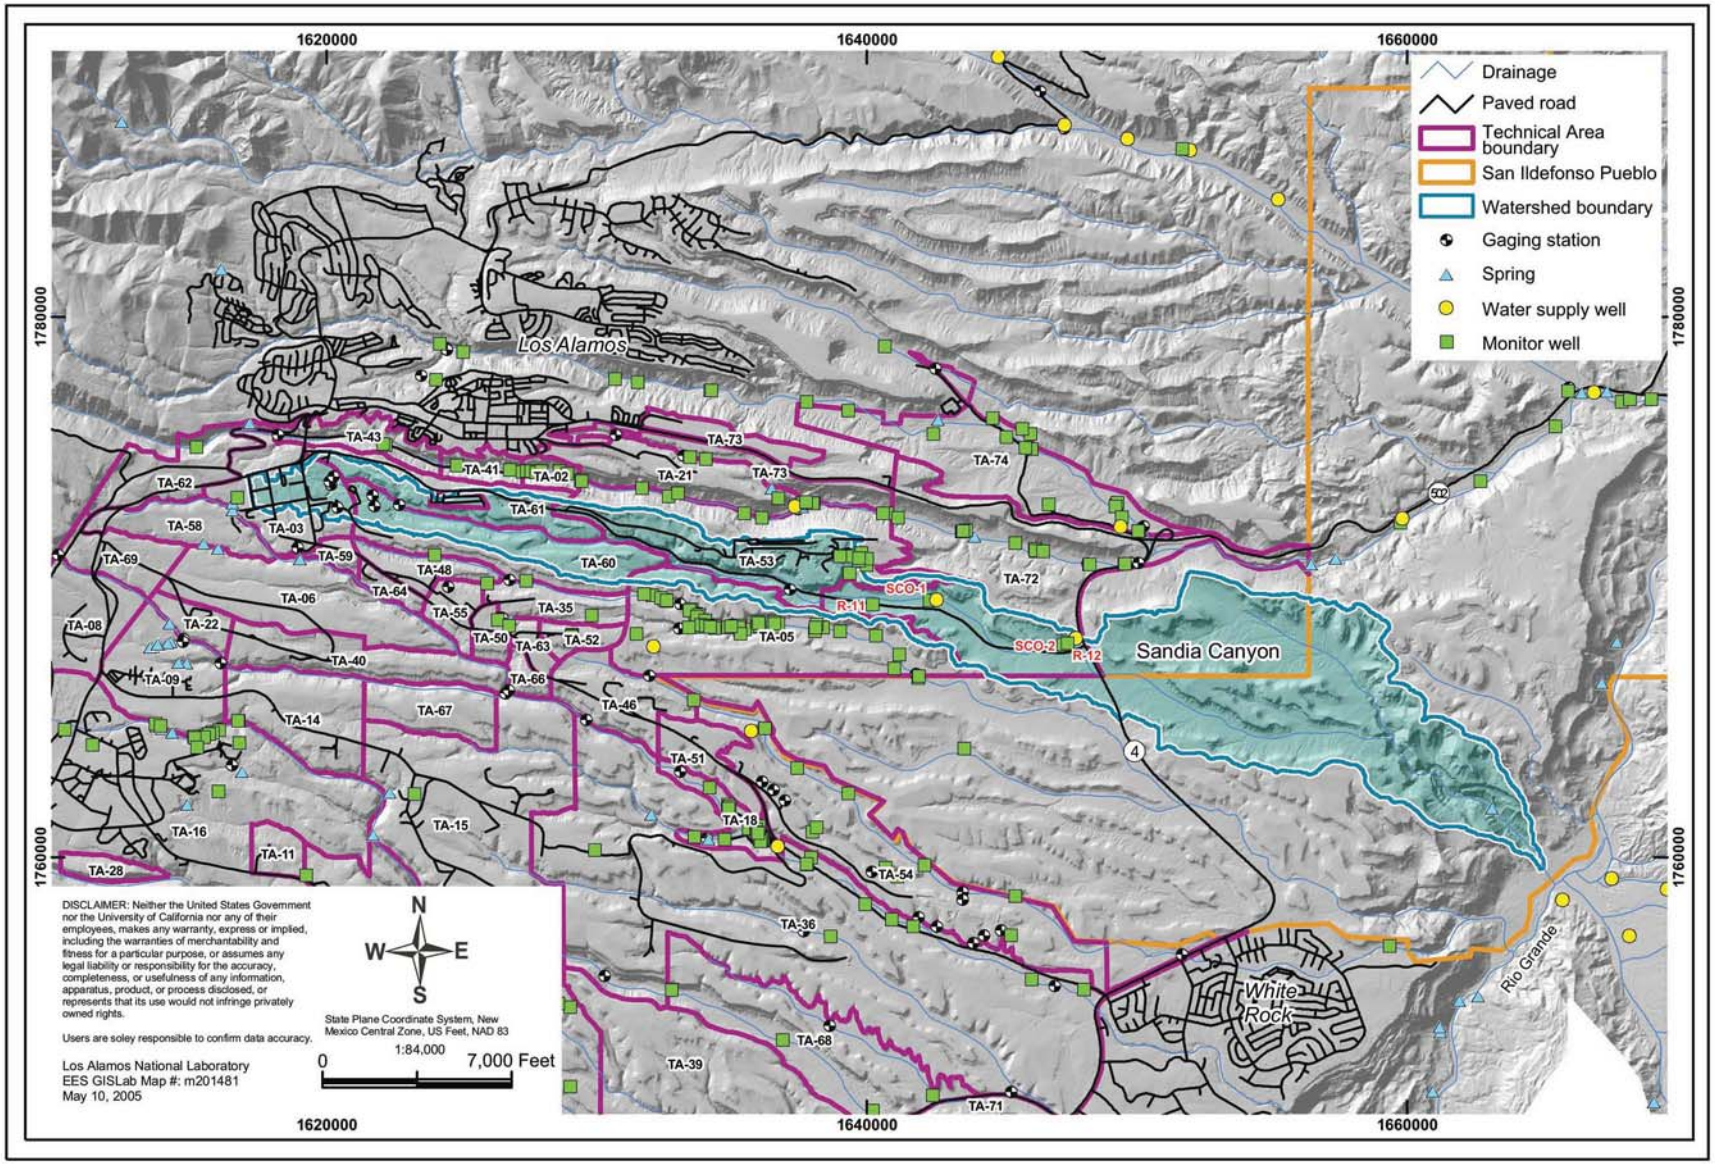

Figure 3-A-4. Sandia Canyon watershed.

Table 3-A-4.
Mortandad Canyon Watershed Description

Hydrogeologic Element	Characteristic	Mortandad Canyon	Cañada del Buey
Surface Water	Flow	Mortandad Canyon is an east to southeast trending canyon that heads on the Pajarito Plateau near the main Laboratory complex at TA-3 at an elevation of 7380 ft above sea level (Figure 3-A-1, Figure 3-A-5). The drainage extends about 9.6 mi from the headwaters to its confluence with the Rio Grande at an elevation of 5440 ft asl covering an area of 5 square miles. The canyon crosses San Ildefonso Pueblo land for several miles before joining the Rio Grande. Tributary canyons to the Mortandad Canyon drainage include Effluent Canyon, Ten Site Canyon, Cedro Canyon, and Cañada del Buey. Surface water in Mortandad Canyon is ephemeral; however, there are two segments that are effluent-dependent. The ephemeral segments flow only in response to precipitation. Historical Environmental Surveillance Program (ESP) data indicate that persistent surface flow occurs in the effluent-dependent segments at the surface water stations down canyon from the Radioactive Liquid Waste Treatment Facility (RLWTF) outfall (measured at gage E200, Mortandad below Effluent Canyon) and the Los Alamos County sewage treatment plant outfall in White Rock.	Cañada del Buey has a drainage area of 4.2 square miles and within the Laboratory boundary, it is ephemeral in character, based on flow data from three gages: E218 (Cañada del Buey near TA-46), E230 (Cañada del Buey above SR-4), and E225 (Cañada del Buey near MDA G). In the period from 1995 to 2002, the number of days of flow per year ranged from 38 at the gage near TA-46 to zero near MDA G. East of LANL in White Rock, Cañada del Buey has effluent-supported flow from the Los Alamos County sewage treatment plant, which discharges into Cañada del Buey about 2 mi upstream of its confluence with Mortandad Canyon and results in effluent-supported surface flow that regularly extends to the Rio Grande.
	Quality	Historically, the following constituents have been detected in Mortandad Canyon surface water at significant levels relative to standards: americium-241, plutonium-238 and plutonium-239, -240, strontium-90, tritium, nitrate, perchlorate, and fluoride.	Operational NPDES-permitted outfalls associated with Cañada del Buey include: 13S associated with the TA-46 SWSC Plant (effluent is sampled at 13S but not discharged; all SWSC effluent is routed to TA-3); and 04A-118 associated with water supply well Pajarito Mesa #4.

Table 3-A-4.
Mortandad Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Mortandad Canyon	Cañada del Buey
Springs	Name	No springs are present in Mortandad Canyon. However, some wetland areas occur in Pratt Canyon and occur locally downstream.	No springs are present in Cañada del Buey.
	Quality	See above.	See above.
Alluvial Groundwater	Extent	The extent, quality, and flow of alluvial groundwater in Mortandad Canyon is known from years of investigations. Major recharge to the alluvium occurs from effluent released in the upper canyon. The alluvial groundwater extends about 2 mi downstream from the TA-50 outfall.	Cañada del Buey contains a shallow perched alluvial groundwater system of limited extent, and only two observation wells here have ever contained water. Purtymun (1995) suggested that the primary source of the alluvial water is purge water from supply well PM-4, although storm water and snowmelt runoff augment the alluvial groundwater. However, the presence of water in the alluvium does not correspond to releases from the water supply wells.
	Depth/Thickness	The saturated portion of the Mortandad Canyon alluvium is generally less than 10 feet thick and there is considerable variation in saturated thickness depending on the amount of precipitation and runoff in any particular year. Groundwater flow velocity in the alluvium varies from about 60 ft/day in the upper canyon to about 7 ft/day in the lower canyon and has been estimated to be 30 to 40 ft/day between MCO-5 and MCO-8.2.	See above.
	Quality	Historically, the following constituents have been detected in alluvial groundwater in Mortandad Canyon at significant levels relative to standards: americium-241; plutonium-238 and plutonium-239, -240; strontium-90; tritium; nitrate; perchlorate; and fluoride. Nitrate (as N) concentrations in alluvial groundwater have generally reflected the concentration in RLWTF effluent. The nitrate concentration in the effluent decreased in 1999 due to improved treatment in the RLWTF,	Some alluvial groundwater samples have contained high levels of gross alpha and gross beta, but have no regular detection of any measured radioisotopes.

Table 3-A-4.
Mortandad Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Mortandad Canyon	Cañada del Buey
		and alluvial groundwater concentrations have fallen below the NM groundwater standard of 10 mg/L as a result. Perchlorate measurements are available since about 2000. The RLWTF started operating a system for removing perchlorate from the plant effluent on March 26, 2002. Prior to removal, perchlorate was measured in RLWTF effluent at an annual average concentration of 169 ppb in 2001; it has not been detected above 4 ppb since. Alluvial groundwater concentrations have fallen rapidly due to effluent improvement. During the last 10 years, tritium has been found above the 20,000 pCi/L EPA MCL at the Laboratory only in alluvial groundwater in Mortandad Canyon. At the end of 2000, the RLWTF adopted a voluntary goal of having tritium activity in its effluent below 20,000 pCi/L, and tritium activity in the effluent dropped below that in 2001 and was 10,400 pCi/L in 2003. Tritium activity in alluvial groundwater downstream has dropped correspondingly with a maximum value of 8,770 pCi/L in 2003. The discharge from the RLWTF into Mortandad Canyon creates a localized area of alluvial groundwater where strontium-90 persists at activities above the 8-pCi/L EPA drinking-water MCL. The radionuclides plutonium-238; plutonium-239, -240; and americium-241 are also present above the 4-mrem DOE DCG for drinking water.	
Intermediate Groundwater	Extent/Hydrology	Perched groundwater was encountered during drilling of R-15 and MCOBT-4.4 in different stratigraphic zones within the	No intermediate perched groundwater has been found in wells drilled near Cañada del Buey. These wells include

Table 3-A-4.
Mortandad Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Mortandad Canyon	Cañada del Buey
		Cerros del Rio basalt. The lateral extent of these intermediate depth perched zones is unknown.	PM-4, R-21, and R-22, as well as numerous wells drilled to investigate conditions beneath MDA L and MDA G.
	Depth/Thickness	Intermediate perched groundwater was found at MCOBT-4.4, where a single screen was set in a perched zone within the upper Puye Formation/Cerros del Rio basalt at a depth of 524 ft below ground surface (bgs). In R-15, perched groundwater was encountered at a depth of 646 ft bgs in the lower portion of the Cerros del Rio basalt.	See above.
	Quality	Measurements from core samples in several wells indicate that there is a large inventory of perchlorate and nitrate in the unsaturated Bandelier Tuff, extending to distances of 400 feet below the floor of Mortandad Canyon. Preliminary estimates suggest there is 415 to 1250 kg of perchlorate in the upper 300 ft of the vadose zone. Analytical results from groundwater samples collected from MCOBT-4.4 showed 12,797 pCi/L tritium, 13.2 mg/L nitrate plus nitrite (as N), and 142 ppb perchlorate. Perched groundwater encountered during the drilling of R-15 contained 3770 pCi/L tritium and 12 ppb perchlorate. Five additional intermediate-depth wells have been drilled and groundwater samples collected from the boreholes near the sediment traps. They contained nitrate, perchlorate, and tritium at concentrations similar to, but less than, those measured at well MCOBT-4.4.	See above.
Regional Aquifer	Depth/Hydrology	The regional water table occurs within the Puye Formation in the four wells that encounter the regional aquifer in the Mortandad Canyon watershed. In Ten Site Canyon, approximately 3700 ft west of the confluence with Mortandad Canyon, the regional aquifer was encountered at a depth of	Regional aquifer conditions for Cañada del Buey are covered in the column for Mortandad Canyon and the table for Pajarito Canyon.

Table 3-A-4.
Mortandad Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Mortandad Canyon	Cañada del Buey
		1182 ft in well R-14. In Test Well 8 the regional aquifer occurs at a depth of 994 ft. The regional aquifer was encountered at a depth of 964 ft in R-15, located in Mortandad Canyon approximately 2000 ft east of the confluence with Ten Site Canyon. In well R-13, located approximately 5800 feet ESE of R-15, the regional aquifer was encountered at a depth of 833 ft. Well R-28 lies between R-15 and R-13 and the regional water table occurs at 889 ft. Flow in the regional aquifer is generally west to east; some deviation may be present due to pumping in the Pajarito Mesa well field. Average flow velocity for the regional aquifer in the vicinity of Mortandad Canyon is estimated to be about 95 ft/yr.	
	Quality	Wells R-13 and R-14 have not shown contamination in the regional aquifer from samples collected during drilling and/or subsequent characterization. Regional aquifer well R-15 contained 2.4 mg/L nitrate (as N), 18 pCi/L tritium, and up to 4.2 ppb perchlorate in groundwater sampled at a depth of 1019 ft bgs. Well R-28 contains 7.2 mg/L of nitrate (as N) in a borehole sample, and 114 pCi/L of tritium.	Well R-21 contained 0.42 pCi/L of tritium and 0.299 µg/L of perchlorate (using liquid chromatography/mass spectrometry. Well R-21 is not impacted from Laboratory discharges.
Contaminants	Potential Sources	The source of contaminants to Mortandad Canyon has been from two liquid waste treatment plants. One is the NPDES-permitted outfall from the TA-50 Radioactive Liquid Waste Treatment Facility. It has been used to treat liquid radioactive waste from Laboratory operations from 1963 to the present. A second radioactive wastewater treatment plant at TA-35 treated wastes from reactor experiments from 1951 to 1963. It did not operate well, and large volumes of wastewater were released into Ten Site Canyon. Other mesa-top sites that could impact Mortandad Canyon	Cañada del Buey is bordered on the south by Material Disposal Areas G and L at TA-54.

Table 3-A-4.
Mortandad Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Mortandad Canyon	Cañada del Buey
		include MDA C near TA-50 and three waste oil surface impoundments at TA-35 closed in 1989. More information about the history of these sites and planned investigations can be found in the RFI Work Plans for OU 1129 and OU 1147.	
	Type	The effluents discharged from TA-3, TA-35, TA-48, and TA-50 have contained a variety of contaminants, including nitrate, perchlorate, tritium, cesium-137, strontium-90, americium-241, and several isotopes of uranium and plutonium.	Past discharges included accidental releases from experimental reactors and laboratories at TA-46. The Los Alamos County sewage treatment plant contributes flow to the lower portion of Cañada del Buey.

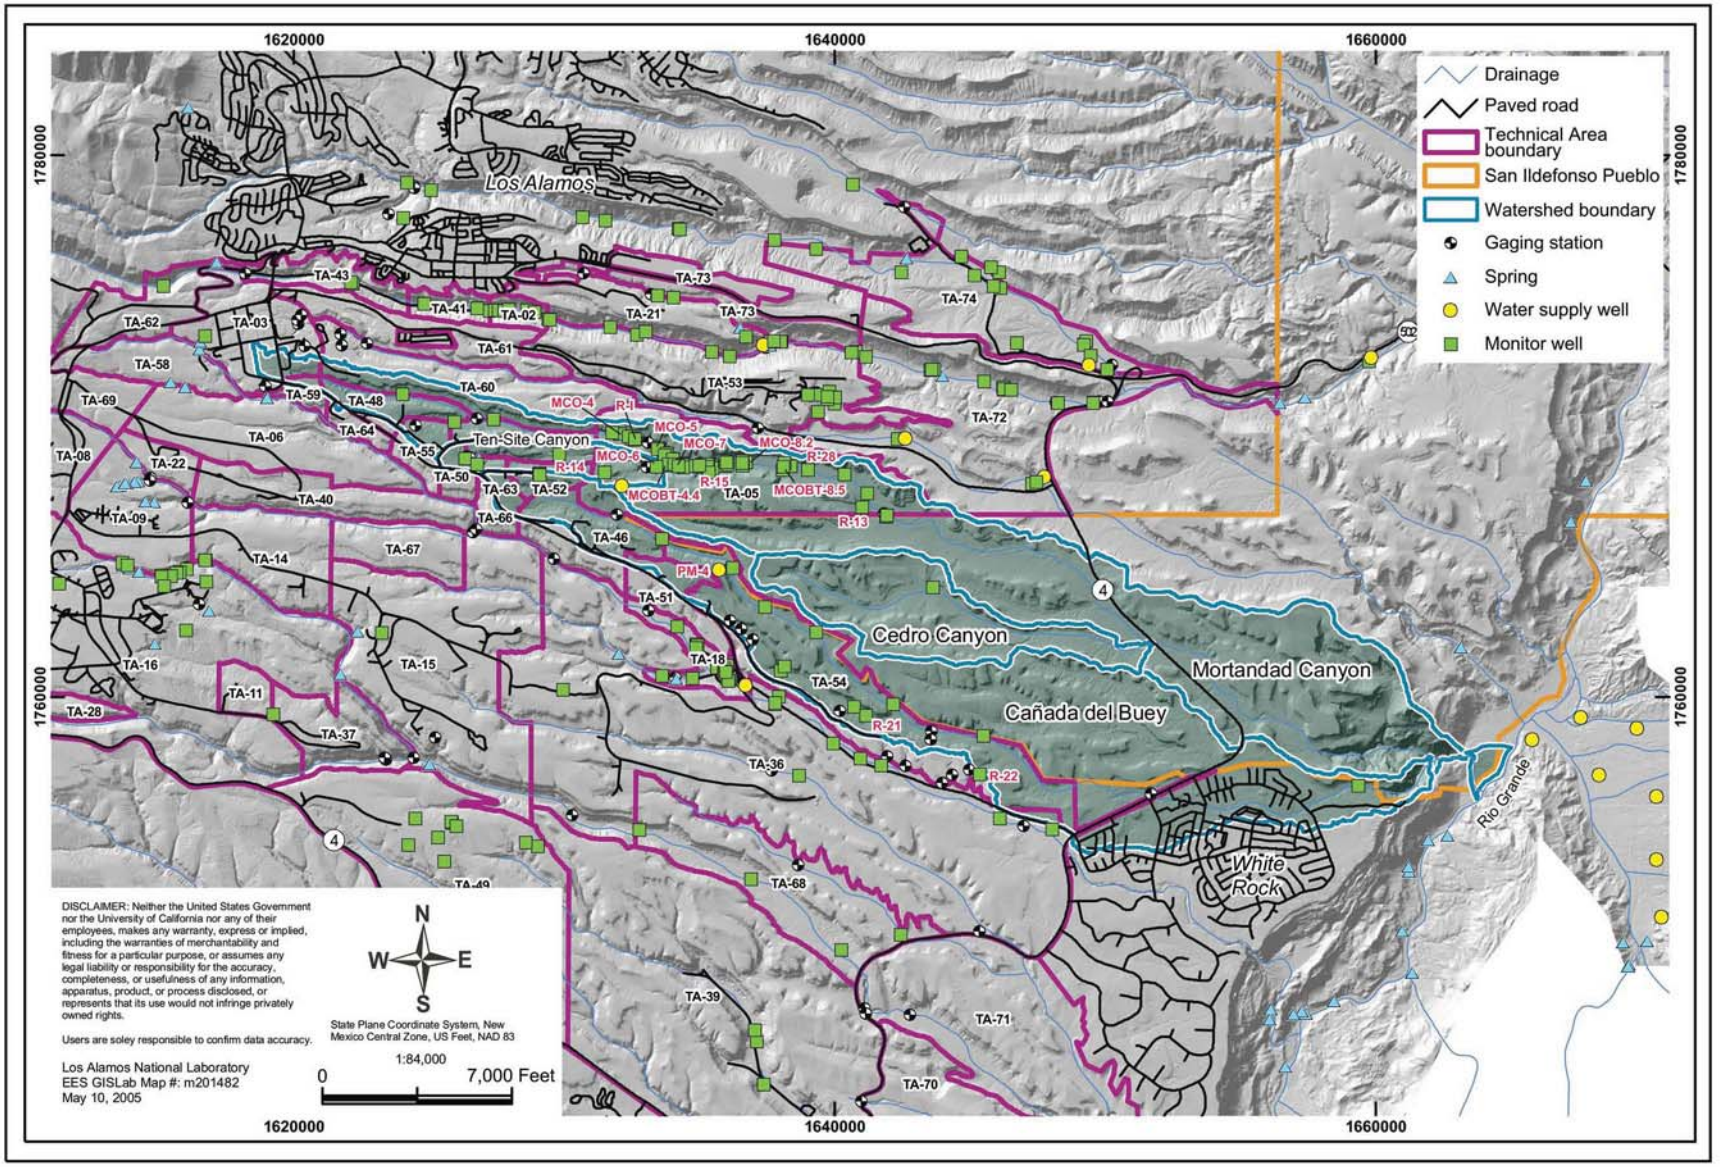

Figure 3-A-5. Mortandad Canyon Watershed including Mortandad Canyon and Cañada del Buey.

Table 3-A-5.
Pajarito Canyon Watershed Description

Hydrogeologic Element	Characteristic	Description
Surface Water	Flow	Pajarito Canyon is located on the Pajarito Plateau in the central part of the Laboratory (Figure 3-A-1; Figure 3-A-6). The canyon heads in the Santa Fe National Forest west of the Laboratory boundary at an elevation of approximately 10,434 ft and trends east-southeast across the Laboratory and Los Alamos County. It empties into the Rio Grande in White Rock Canyon at an elevation of 5422 ft. The drainage area of the Pajarito Canyon watershed is about 12 square miles. Surface water occurs in Pajarito Canyon mostly as intermittent flow. Short reaches of perennial flow occur downstream of spring discharges in Starmers Gulch and below Spring 4A in White Rock Canyon. Surface water flow is ephemeral in central Pajarito Canyon between the confluences with Twomile and Threemile Canyons. Flow is also ephemeral through White Rock. In Twomile Canyon, flow is ephemeral west of TA-3 and is possibly intermittent from TA-3 to the confluence with Pajarito Canyon. Three-mile Canyon is ephemeral except for a possible intermittent reach supported by springs above the confluence of Three-mile and Pajarito Canyons.
	Quality	High explosive compounds and metals have been detected in surface water in upper and middle Pajarito Canyon. There are no surface water chemistry results for Twomile Canyon except for a small tributary near building SM-30 in TA-3. Samples from the tributary show elevated arsenic and mercury in nonfiltered samples. RDX, SVOCs, and pesticides have been detected in a surface water sample in Threemile Canyon.
Springs	Name	Short reaches of perennial flow occur down stream of spring discharges in Starmers Gulch and below Spring 4A in White Rock Canyon. In the western portion of Pajarito Canyon, springs discharge from canyon slopes above the alluvium. The probable source of these springs is groundwater perched within the upper part of the Tshirege Member of the Bandelier Tuff. Typical discharge rates are approximately 1 to 15 gallons per minute. Springs include PC, Homestead, Upper Starmer, Charlies, Garvey, Perkins, Starmer, Josie, Keiling, and Bulldog Springs. Springs issue from the canyon floor of upper Twomile Canyon in TA-3 and TA-58. These springs include Hanlon, Anderson, SM-30, SM-30A, and TW-1.72 Springs. There are two springs in the floor of Threemile Canyon (Threemile and TA-18 Springs).

Table 3-A-5.
Pajarito Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Description
	Quality	HE compounds have been detected in spring water at TA-8 and TA-9. There are no screening data for springs in Twomile Canyon. HE compounds have been detected in Threemile Canyon.
Alluvial Groundwater	Extent	There are no alluvial wells in Pajarito Canyon upstream of TA-18. Therefore, information about the nature and extent of alluvial groundwater is limited. Most likely, infiltration of surface water creates a continuous saturated zone within the alluvium that extends from the Pajarito fault zone across the Laboratory to White Rock. Alluvial wells have been installed between TA-18 and state road NM4, which demonstrate the presence of alluvial groundwater in this part of Pajarito Canyon. The drilling of seven test holes in 1985 showed that the saturation in lower Pajarito Canyon does not extend laterally under Mesita del Buey near MDAs G and L. Three of the alluvial test holes were completed as groundwater monitoring wells (PCO-1, -2, -3). An additional 20 alluvial wells were installed between 1990 and 1998 by the Environmental Restoration Project as part of the RFI for TA-18. There are no alluvial wells in Twomile Canyon and the extent of alluvial groundwater, if present, is unknown. There are no alluvial wells in Twomile Canyon and the extent of alluvial groundwater, if present, is unknown. Alluvial groundwater has been documented in lower Threemile Canyon at 18-BG-1 and 18-MW-8.
	Depth/Thickness	Wells PCO-1, -2, and -3 are probably representative of alluvial groundwater between TA-18 and state road NM-4. When installed during 1985, depth to water was 1.3 ft in PCO-1, 6.3 ft in PCO-2, and 3.1 ft in PCO-3. Assuming continuous saturation in the alluvium, the saturated thickness is about 9.7 ft in PCO-1, 2.7 ft in PCO-2, and 8.9 ft in PCO-3. The saturated thickness and presence of water in these wells vary seasonally. Due to drought, these wells have had little water since 2000. At well 18-BG-4 in Threemile Canyon, the water level was 2.5 ft bgs.
	Quality	Data indicate the presence of metals, radionuclides, high explosives, VOCs, and anions in alluvial groundwater. Except for VOCs and some radionuclides in wells near TA-18, occurrence of these constituents is irregular and at low levels. There are no water quality data for alluvial groundwater in Twomile Canyon. Alluvial groundwater has been documented in lower Threemile Canyon at 18-BG-1 and 18-MW-8. In lower Threemile Canyon RDX and VOCs have been detected in 18-MW-8.
Intermediate Groundwater	Extent/Hydrology	Intermediate perched water is likely to occur beneath Pajarito Canyon, but knowledge of its extent and quality is incomplete. No water quality data for perched intermediate systems are available with current wells. Perched water was suggested during the drilling of PM-2 and SHB-4 in the vicinity of TA-18. At PM-2, a “show of water at 335 ft” was noted in the Otowi Member of the Bandelier Tuff during the cable-tool drilling. In SHB-4, the core tube and core from the top of the

Table 3-A-5.
Pajarito Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Description
		Otowi Member from about 125 ft to 145 ft came out of the hole wet. Test Holes 5 and 6 were drilled in 1950 to investigate perched groundwater in Pajarito Canyon south of TA-54. Test Hole 5 was drilled through the Bandelier Tuff and into basalts at a total depth of 263 ft. Test Hole 6 was also drilled through the tuff and into basalts to a total depth of 300 ft. These dry test holes indicate that perched water does not occur in the upper part of the vadose zone in this part of the canyon. Between 2000 and 2002 regional wells R-20, R-22, R-23, and R-32 were installed in lower Pajarito Canyon. Perched intermediate water was not identified during the drilling of wells R-20, R-22, and R-32. At R-23, near the eastern Laboratory boundary, there were indications that perched intermediate water may be present in Cerros del Rio basalt. However, R-23 is only screened in the regional aquifer. In Twomile Canyon, well 03-MW-1 is a 28-ft-deep mesa top well that samples shallow intermediate perched water near building SM-30 at TA-3. A thin zone of saturation occurs in the upper Tshirege Member. Characterization well R-19, located on the mesa south of Threemile Canyon, had indications of possible perched water at depths of 834 to 840 ft and 894 to 912 ft. Both zones were screened in the completed well, but only the 894 to 912 ft interval (screen 2) in the Puye Formation yields water.
	Depth/Thickness	See above.
	Quality	Characterization sampling for 03-MW-1 found elevated concentrations of Hg, tritium, and VOCs. A RFI Work Plan is being prepared to determine the extent of this perched zone. Four rounds of characterization sampling for R-19 indicate there are no impacts to the intermediate perched water from Laboratory operations. Less than detection activities of tritium indicate that groundwater in the perched zone pre-dates atmospheric nuclear testing.
Regional Aquifer	Depth/Hydrology	Water-level maps indicate that in the vicinity of Pajarito Canyon the general direction of groundwater flow in the regional aquifer is east to southeast. Depth to the regional aquifer is known in Pajarito Canyon at supply well PM-2 and in characterization wells R-20, R-22, R-23, and R-32. The nonpumping water level for PM-2 in 2001 was at a depth of 855 ft. In 2002, the regional water table was at a depth of 826 ft in R-20, 890 ft in R-22, 828 ft in R-23, and 776 ft in R-32. R-23 is completed with a single well screen, R-20 and R-32 have three well screens, and R-22 has five well screens. The regional aquifer probably discharges at Spring 4A and other springs along White Rock Canyon. There are no regional aquifer wells associated with Twomile Canyon. Well R-19 is located on the mesa south of Threemile

Table 3-A-5.
Pajarito Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Description
		Canyon. It is down gradient from firing site IJ in TA-36 and is up gradient of TA-18. In addition to two screens in the vadose zone (described above), R-19 has five screens in the regional aquifer.
	Quality	Water quality of the regional aquifer beneath eastern Pajarito Canyon shows little, if any, impacts from LANL operations. Four rounds of characterization sampling at R-22 yielded possible detects of Tc-99 in the first sampling round for screens 3 and 4, but it was not detected in any of the screens during subsequent sampling rounds. Tritium was detected above background (~1 pCi/L) in screen 2 (76.6 pCi/L) during the first sampling round, but was at background for subsequent sampling rounds. Tritium activities in screen 5 were slightly elevated relative to background in the four characterization sampling rounds (3.5 to 18.5 pCi/L). Surveillance sampling of PM-2 shows the groundwater meets regulatory standards. Wells R-20 and R-32 contained low levels of tritium less than 3 pCi/L (1.98 pCi/L of tritium for well R-20 and 2.84 pCi/L for well R-32). Followup sampling at well R-32 did not confirm the presence of low-level tritium. Low-level perchlorate was not detected at well R-20 and was detected at wells R-23 (0.21 to 0.41 µg/L) and well R-32 (0.21 to 0.29 µg/L). Results for both low-level tritium and low-level perchlorate for these three wells suggest that the regional aquifer is not significantly impacted from Laboratory discharges. The dominant fraction of groundwater in the regional aquifer is greater than 61 years of age, based on the non-detectable tritium. Four rounds of characterization sampling at R-19 indicate there are no impacts to the regional groundwater from Laboratory operations. Less than detection activity of tritium at R-19 indicate that the regional groundwater pre-dates nuclear testing.
Contaminants	Potential Sources	The primary Laboratory use of Pajarito Canyon watershed has been as the canyon-bottom location for the Los Alamos Critical Experiments Facility (LACEF) at TA-18 and for mesa-top surface and subsurface material disposal areas (MDAs) F at TA-6, Q at TA-8, MDA M at TA-9, and MDAs G, H, J, and L at TA-54. Runoff from firing sites in TA-15 and TA-36 may also be a contaminant source. A detailed description and data summary for Pajarito Canyon potential contaminants is contained within the work plan for Pajarito Canyon.
	Type	Pajarito Canyon: metals, radionuclides, HE compounds, VOCs, anions; Twomile Canyon: mercury, tritium, VOCs; Threemile Canyon: HE compounds, VOCs.

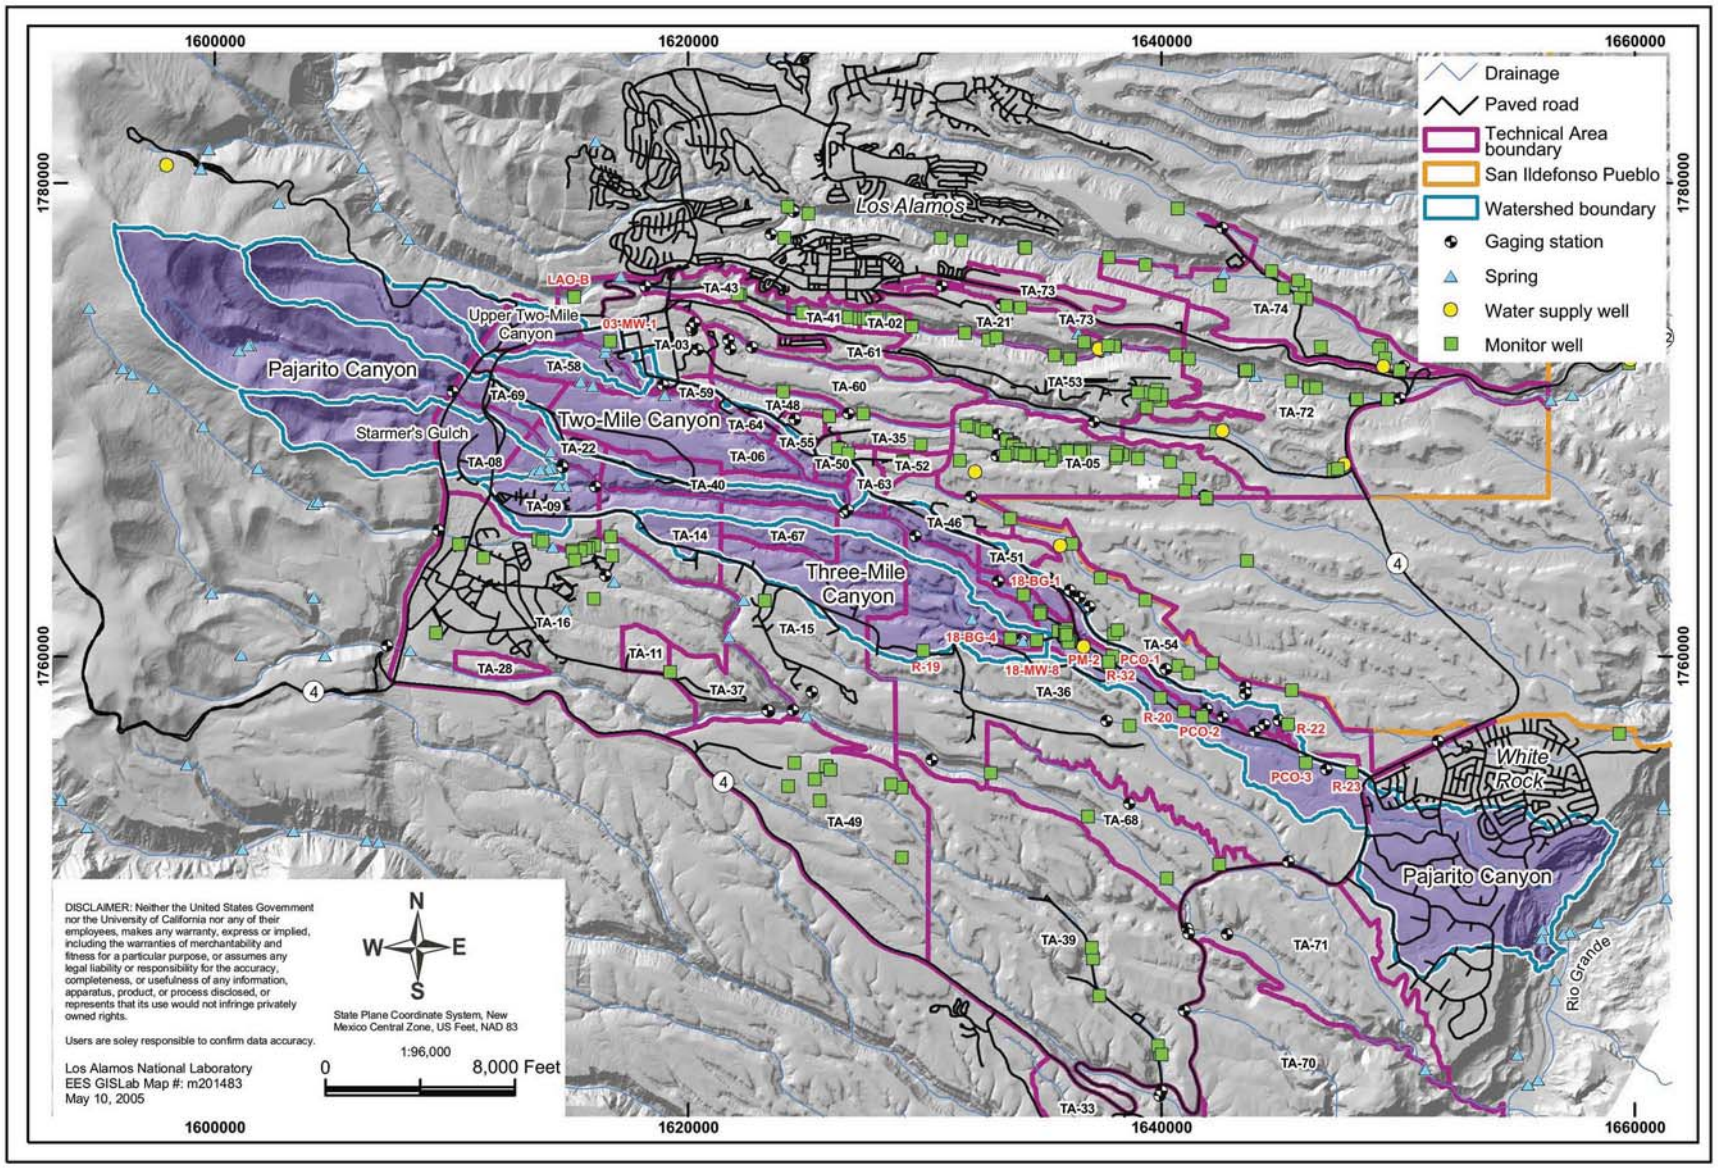

Figure 3-A-6. Pajarito Canyon watershed.

Table 3-A-6.
Water Canyon Watershed Description

Hydrogeologic Element	Characteristic	Water Canyon	Cañon de Valle	Potrillo and Fence Canyons
Surface Water	Flow	The Water Canyon drainage area is about 6 square miles. Surface water flow in upper Water Canyon is perennial from SR 501 to the eastern edge of TA-28 (Figure 3-A-1, Figure 3-A-7). Intermittent surface water occurs in upper Water Canyon (gage E252, Water above SR-501), primarily in the spring. In middle Water Canyon, flow is ephemeral at gage station E265.2 (Water below SR-4). Lower Water Canyon is ephemeral.	Cañon de Valle has a drainage area of 4 square miles and surface water is perennial from Burning Ground spring to gage E256 (Cañon de Valle below MDA P). Intermittent surface water occurs from natural and anthropogenic sources to gage E262 (Cañon de Valle above Water) Figure 3-A-1, Figure 3-A-7).	The drainage area of Potrillo Canyon and Fence Canyon together is about 4.5 square miles and the surface water flow is entirely ephemeral.

Table 3-A-6.
Water Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Water Canyon	Cañon de Valle	Potrillo and Fence Canyons
	Quality	Except for flow from the Water Canyon Gallery, no surface water quality data are available for upper Water Canyon. In middle Water Canyon, surface water chemistry results show contaminant levels are at detection or background levels. In lower Water Canyon, uranium is significantly greater than background in surface water (>10 ppb) near the firing sites, yet no significant elevation in concentration is seen at State Road 4.	Surface water concentrations of barium are 2-3 mg/L and concentrations of RDX are more than 100 µg/L or ppb.	See above.
Springs	Name	Water Canyon Gallery is a spring that issues from the Bandelier Tuff west of LANL in Water Canyon. Spring 5A is in lower Water Canyon.	Several springs issue from the Bandelier Tuff in the upper reaches of Cañon de Valle: Armistead Spring, American Spring (west of LANL) and SWSC, Burning Ground, Martin, and Hollow Springs, and others (in LANL). Note that Martin Spring actually flows into Water Canyon. It is included here because of its close location to the Cañon de Valle springs, and similar contaminant constituents.	There are no springs in Potrillo Canyon or Fence Canyon.
	Quality	Water quality data indicate that concentrations of constituents are consistent with other springs within the Sierra de los Valles.	For the on site springs, chloride, sodium, manganese, nitrate, barium, boron, HE compounds, and solvents are at concentrations above background. As in the alluvial system, the main contaminants of concern are HE compounds and barium. HMX, RDX, and TNT concentrations range	See above.

Table 3-A-6.
Water Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Water Canyon	Cañon de Valle	Potrillo and Fence Canyons
			up to 32, 330, and 3 µg/L, respectively. Barium concentrations range up to 1310 µg/L. Martin and Fishladder canyons are above 6.1 ppb RDX as well.	
Alluvial Groundwater	Extent	In upper Water Canyon, some alluvial groundwater is likely to occur near the headwaters. The occurrence and duration of alluvial groundwater likely decreases down canyon, given limited addition of water, lack of springs and seeps, and rare discharge from tributary canyons. Alluvial groundwater in Martin Canyon (a small tributary canyon to Water Canyon) is intermittent. In middle Water Canyon, alluvial groundwater is present in WCM-1 and WCM-2, but no water is present in WCO-1, WCO-2, and WCO-3. The downstream extent of alluvial groundwater may be between the WCM-2 and WCO-1.	A thin (typically <10 ft thick) alluvial system in Cañon de Valle near SWSC and Burning Ground Springs has perennial saturation. However, alluvial saturation does not extend to the confluence with Water Canyon. The down-canyon extent of saturation is highly variable and fluctuates depending on weather conditions. Saturation is also restricted by the limited extent of alluvium in the canyon. Six alluvial wells are used for water level monitoring and for alluvial water sampling.	In Potrillo Canyon, there is one known occurrence of alluvial groundwater in moisture access hole POTM-2. Several other boreholes have been drilled near this area to define the extent of the groundwater found in POTM-2 but all are dry. In Fence Canyon, no occurrences of alluvial groundwater have been documented. However, only one well was installed, well FCO-1, located near State Road 4. Based on physiography, no alluvial groundwater is expected at that location.
	Depth/Thickness	The alluvium is typically less than 10 ft thick.	See above.	See above.
	Quality	Groundwater quality in Martin Canyon shows primarily barium and high explosives as contaminants but also nitrate, many metals and organics, including values above WQCC standards.	Groundwater quality shows primarily barium and HE compounds including HMX, RDX, and TNT as contaminants. HMX, RDX, and TNT concentrations have been measured up to 610, 759, and 46 µg/L, respectively. High explosive degradation products and perchlorate	See above.

Table 3-A-6.
Water Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Water Canyon	Cañon de Valle	Potrillo and Fence Canyons
			have also been detected. Barium concentrations range up to 18,000 µg/L.	
Intermediate Groundwater	Extent/Hydrology	No perched water was encountered in any of the holes and all holes have remained dry with the exception of core hole CH-2. DT-5, DT-5P, and four core holes (CH-1, CH-2, CH-3, and CH-4) were drilled to depths of 300 to 500 ft at the main experimental area and more than 50 experimental holes were drilled as deep as 142 ft in Areas 1, 2, 2A, 2B, 3, and 4 from 1959 to 1961. CH-2 may have an undetected natural perched zone; however, this seems unlikely because this recharge pathway apparently developed more than a decade after the hole was completed.	At depths of a few hundred feet, transient zones of perched saturation within the Bandelier Tuff have been identified in two boreholes beneath the TA-16 mesa between Water Canyon and Cañon de Valle. These zones may be related to the perched water that feeds the numerous Cañon de Valle springs.	No perched zones are known in the area of these canyons, although little drilling has been done.
	Depth/Thickness	See above.	Wells R-25 and SHB-3 encountered a thick perched zone in the lower Otowi and upper Puye that apparently extends beneath a large portion of the mesa; at R-25 the perched zone extends in depth from 711 to 1132 ft. The lateral extent of this perched zone has not been determined, however.	See above.
	Quality	See above.	The transient saturation contains HE and barium contamination and appears to be from former and active HE waste water lagoons on the mesa top rather than to the building 260	See above.

Table 3-A-6.
Water Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Water Canyon	Cañon de Valle	Potrillo and Fence Canyons
			outfall. HMX, RDX, and TNT concentrations range up to 21, 2 490, and 1.3 µg/L, respectively. Barium concentrations range up to 1790 µg/L. High explosive compounds (for example, 84 µg/L RDX), HE degradation intermediates (2-amino-4,6-dinitro-toluene and 4-amino-2,6-dinitrotoluene), chlorinated solvents, and boron were detected in the perched zone at R-25. The tritium activity in this well is up to 140 pCi/L in the intermediate perched zone, indicating a component of recharge within the last 50 years. The unsaturated soils and tuff that make up the TA-16 mesa, and the alluvial sediments and soils of Cañon de Valle and Martin Canyon contain variable and localized inventories of HE and barium. Core holes in the vicinity of the 260 outfall in particular show detections of these contaminants in the upper few hundred feet of the vadose zone.	
Regional Aquifer	Depth/Hydrology	Information on the regional aquifer near Water Canyon is discussed in the table for Ancho Canyon.	Well R-25 encountered the regional aquifer at 1286 ft.	By projecting depths from water supply well PM-2, the regional aquifer lies 730 ft below the bottom of Potrillo Canyon and 620 ft below the bottom of Fence Canyon.
	Quality	See above.	High explosives were detected in R-25 although this may have been from	See above.

Table 3-A-6.
Water Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Water Canyon	Cañon de Valle	Potrillo and Fence Canyons
			cross contamination from the upper saturated zone above, which occurred during drilling (Longmire 2005). High explosives concentrations are decreasing in the regional aquifer samples with time, while they are remaining relatively constant in the upper saturated zone. Tritium activity has decreased during sampling, remaining above 2 pCi/L, suggesting a component of recharge in the past 61 years. Well R-18 located north of well R-25 contained less than -0.32 pCi/L of tritium, less than 0.001 ppm of perchlorate, and concentrations of HE compounds and degradation intermediates were less than detection (0.48 to 1.5 µg/L method detection limit). Well R-18 has not experienced recharges within the past 61 years and the well is not impacted from Laboratory discharges.	
Contaminants	Potential Sources	In upper Water Canyon, potential contaminant sources include TA-11, TA-15, and TA-16. Potential contaminants include HE compounds, barium, and solvents. In middle Water Canyon, TA-49 is a potential contaminant source possibly contributing isotopes of uranium and plutonium, lead, beryllium, and HE compounds such as TNT, RDX, HMX,	In Cañon de Valle, potential contaminant sources include TA-8, TA-9, TA-11, TA-14, TA-15, and TA-16.	In Fence Canyon and Potrillo Canyon, firing sites at TA-36 are potential sources of contaminants.

Table 3-A-6.
Water Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Water Canyon	Cañon de Valle	Potrillo and Fence Canyons
		and barium nitrate. For lower Water Canyon, TA-14, TA-15, and TA-36 are potential sources of high explosives such as TNT, nitrocellulose, trinitramines (RDX), and pentaerythritol tetranitrate (PETN). Metals may also be associated with the explosives (uranium, barium, beryllium, lithium hydride, lead, mercury, copper, and zinc).		
	Type	Soils in several of these operational areas have high levels of uranium contamination. More information for upper Water Canyon may be found in the RFI Work Plan for Operable Unit 1082. For middle and lower Water Canyon, additional detail is contained in the RFI Work Plan for Operable Unit 1144 and RFI Work Plans for Operable Units 1085, 1086, and 1130.	Potential contaminants include HE compounds, barium, nitrate, and solvents. More information may be found in the RFI Work Plan for Operable Unit 1082 and the associated RFI reports.	TNT, nitrocellulose, trinitramines (RDX), and PETN. Metals may also be associated with the explosives (uranium, barium, beryllium, lithium hydride, lead, mercury, copper, and zinc). Soils in several of these operational areas have high levels of uranium contamination.

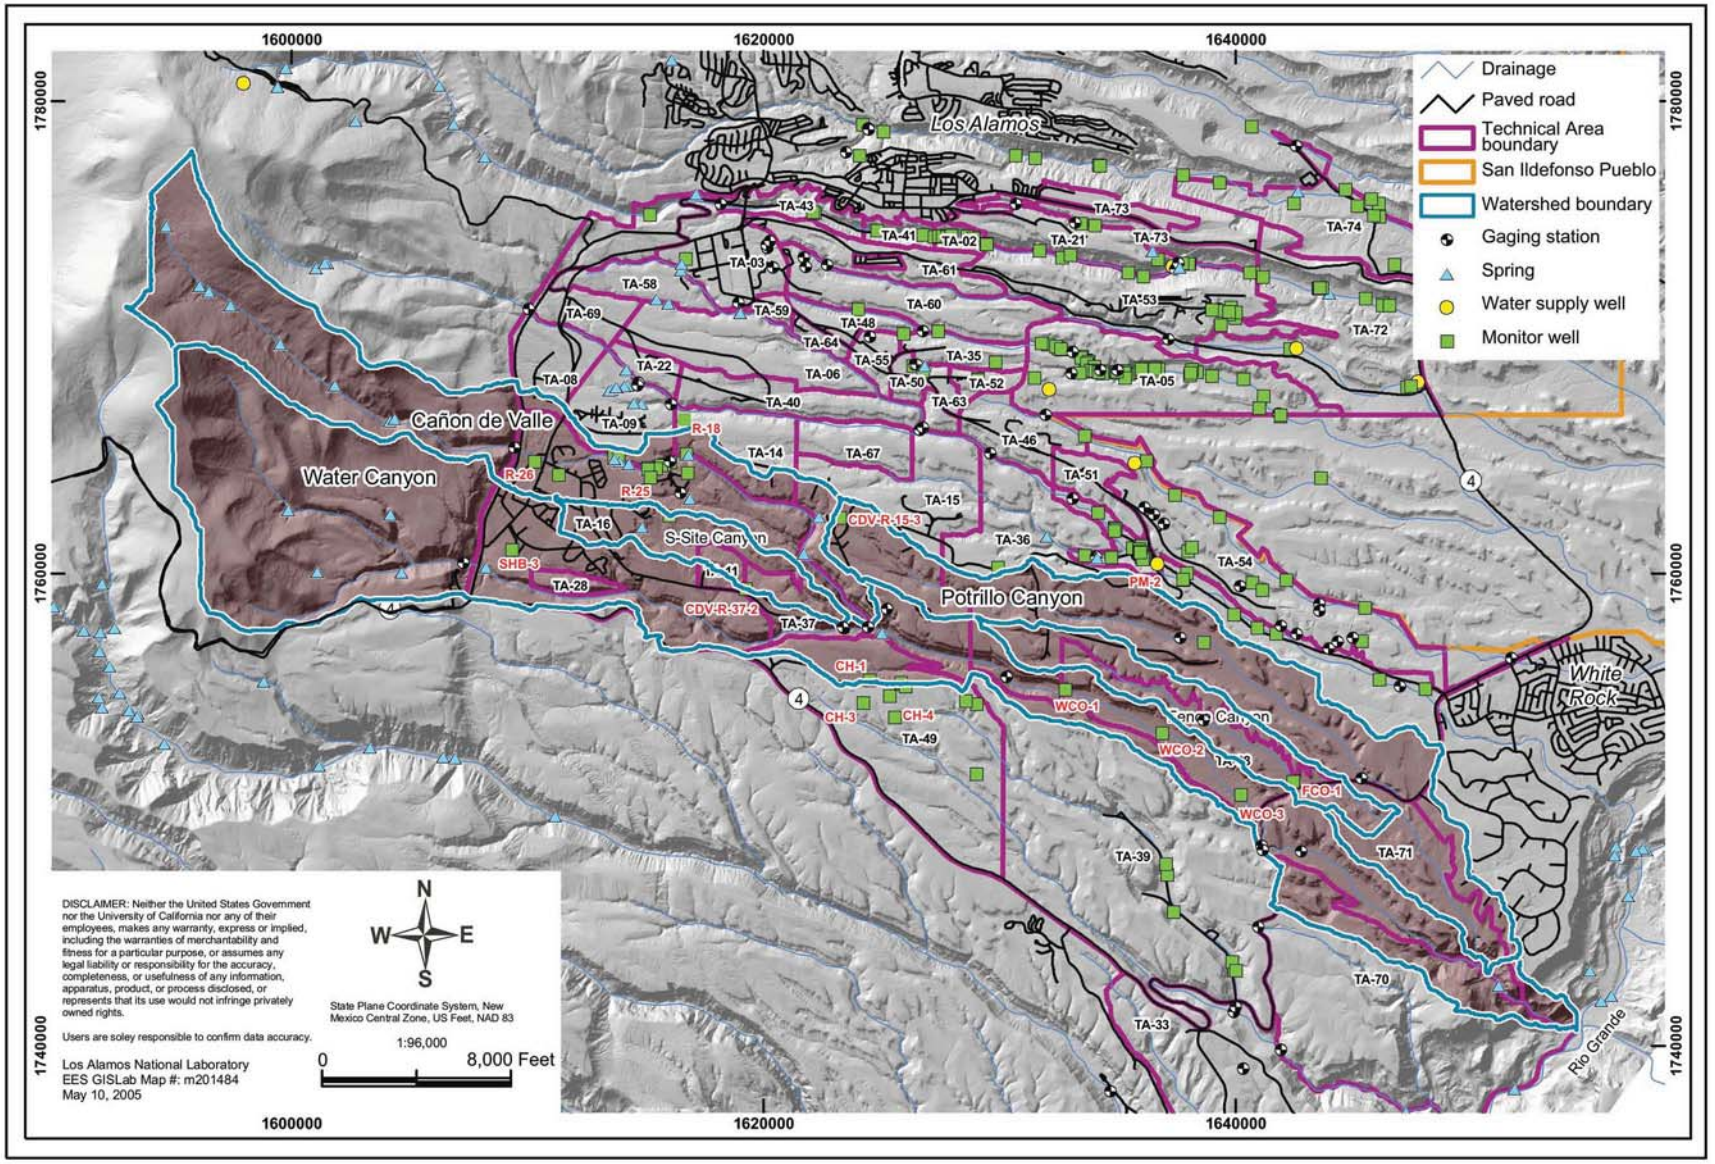

Figure 3-A-7. Water Canyon watershed including Pajarito Canyon, Cañon de Valle, Potrillo Canyon, and Fence Canyon.

Table 3-A-7.
Ancho Canyon Watershed Description

Hydrogeologic Element	Characteristic	Description
Surface Water	Flow	Ancho Canyon lies in the southeastern part of the Laboratory (Figure 3-A-1; Figure 3-A-8) and has a drainage area of 6.7 square miles. Ancho Canyon heads on the Pajarito Plateau and for the most part has ephemeral flow. The canyon has two main branches. Beginning less than a mile above the Rio Grande, flow in Ancho Canyon is perennial, fed by Ancho Spring, a regional aquifer spring.
	Quality	
Springs	Name	Ancho Spring
	Quality	Analysis of water at Ancho Spring by the Environmental Surveillance Program indicates occasional presence of HE compounds and trace levels of depleted uranium. Because the spring issues from the canyon floor, it is uncertain whether these contaminants are being transported by groundwater or if they are being mobilized from sediments in the canyon. Ancho Spring is downgradient of explosives testing sites.
Alluvial Groundwater	Extent	Little is known about the presence of alluvial groundwater in Ancho Canyon. Ancho Canyon contains thick alluvium that could host perched groundwater.
	Depth/Thickness	Three boreholes (ASC-15, ASC-16, and ASC-18) drilled by the ER Project encountered 4 ft to 9 ft of saturation in alluvium below MDA Y, but no contamination. Several boreholes drilled downgradient of MDA Y did not encounter alluvial groundwater, suggesting that the occurrence of alluvial groundwater in this area is limited in extent.
	Quality	See above.
Intermediate Groundwater	Extent/Hydrology	No intermediate perched zones have been found beneath Ancho Canyon. ER borehole DMB-1, drilled between building 69 and the Administrative Area at TA-39, penetrated 119 ft of Bandelier Tuff and 5 ft of Cerros del Rio basalts. No intermediate-depth perched water was encountered in this hole, but clay-lined fractures and vesicles in the basalt suggest that the periodic passage of groundwater through these rocks may occur. A test hole (TH-7) drilled 10 ft into basalts in Ancho Canyon below State Road 4 was dry. The hole was drilled in 1950 and has been plugged.
	Depth/Thickness	R-31 was drilled in TA-39 in the north fork of Ancho Canyon. A screen was placed from 439 to 454 ft at a possible perched zone, based on water seen in a borehole video. The zone has been dry since and no water samples have been collected from it.

Table 3-A-7.
Ancho Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Description
	Quality	See above.
Regional Aquifer	Depth/Hydrology	Groundwater flow in the regional aquifer beneath Ancho Canyon is to the east and southeast, towards the Rio Grande. The regional aquifer lies at about 1000 to 1170 ft beneath the mesa at TA-49, and is within the Cerros del Rio basalt, the underlying Puye Fanglomerate, "Totavi" gravels, and possibly the Santa Fe Group (Section 2.3.1). The regional water table, at well R-31 in TA-39, was encountered at about 530 ft within the Cerros del Rio basalt, the underlying Puye Fanglomerate, and "Totavi" gravels.
	Quality	Three regional aquifer wells at TA-49 have been sampled since the 1960s to monitor for effects of testing at that site. In general, no contaminants have been consistently found. High metal concentrations (lead, zinc, iron, manganese) in samples are related to metal well casing and fittings. Occasional detections of organic compounds are not supported by follow up sampling. Post-drilling water quality sampling has not been completed at well R-31.
Contaminants	Potential Sources	Located south of Ancho Canyon on a mesa near the Rio Grande, TA-33 was used as a firing site and for production of tritium. PRSs include landfills, septic systems, and burn areas. It is situated on a mesa top and is being investigated by the ER Project as OU 1122. TA-39 is located on the floor of middle Ancho Canyon, and it was used for open-air testing of high explosives. PRSs in this technical area include five firing sites, a number of landfills, and septic systems. The ER Project is investigating this technical area as OU 1132. More detailed information about the operational history and the PRSs can be found in the RFI Work Plans for OUs 1122 and 1132. TA-49 lies on a mesa in the upper part of the Ancho Canyon drainage. TA-49 was used for underground hydronuclear testing in the early 1960s. The testing consisted of criticality, equation of state, and calibration experiments involving special nuclear materials. The RFI Work Plan for Operable Unit 1144 describes the planned ER investigations that focus on identifying and quantifying migration of contaminants from the shafts.
	Type	There are large inventories of radioactive and hazardous materials such as isotopes of uranium and plutonium, lead, beryllium, TNT, RDX, HMX, and barium nitrate. Much of this material was left in shafts drilled into the mesa top.

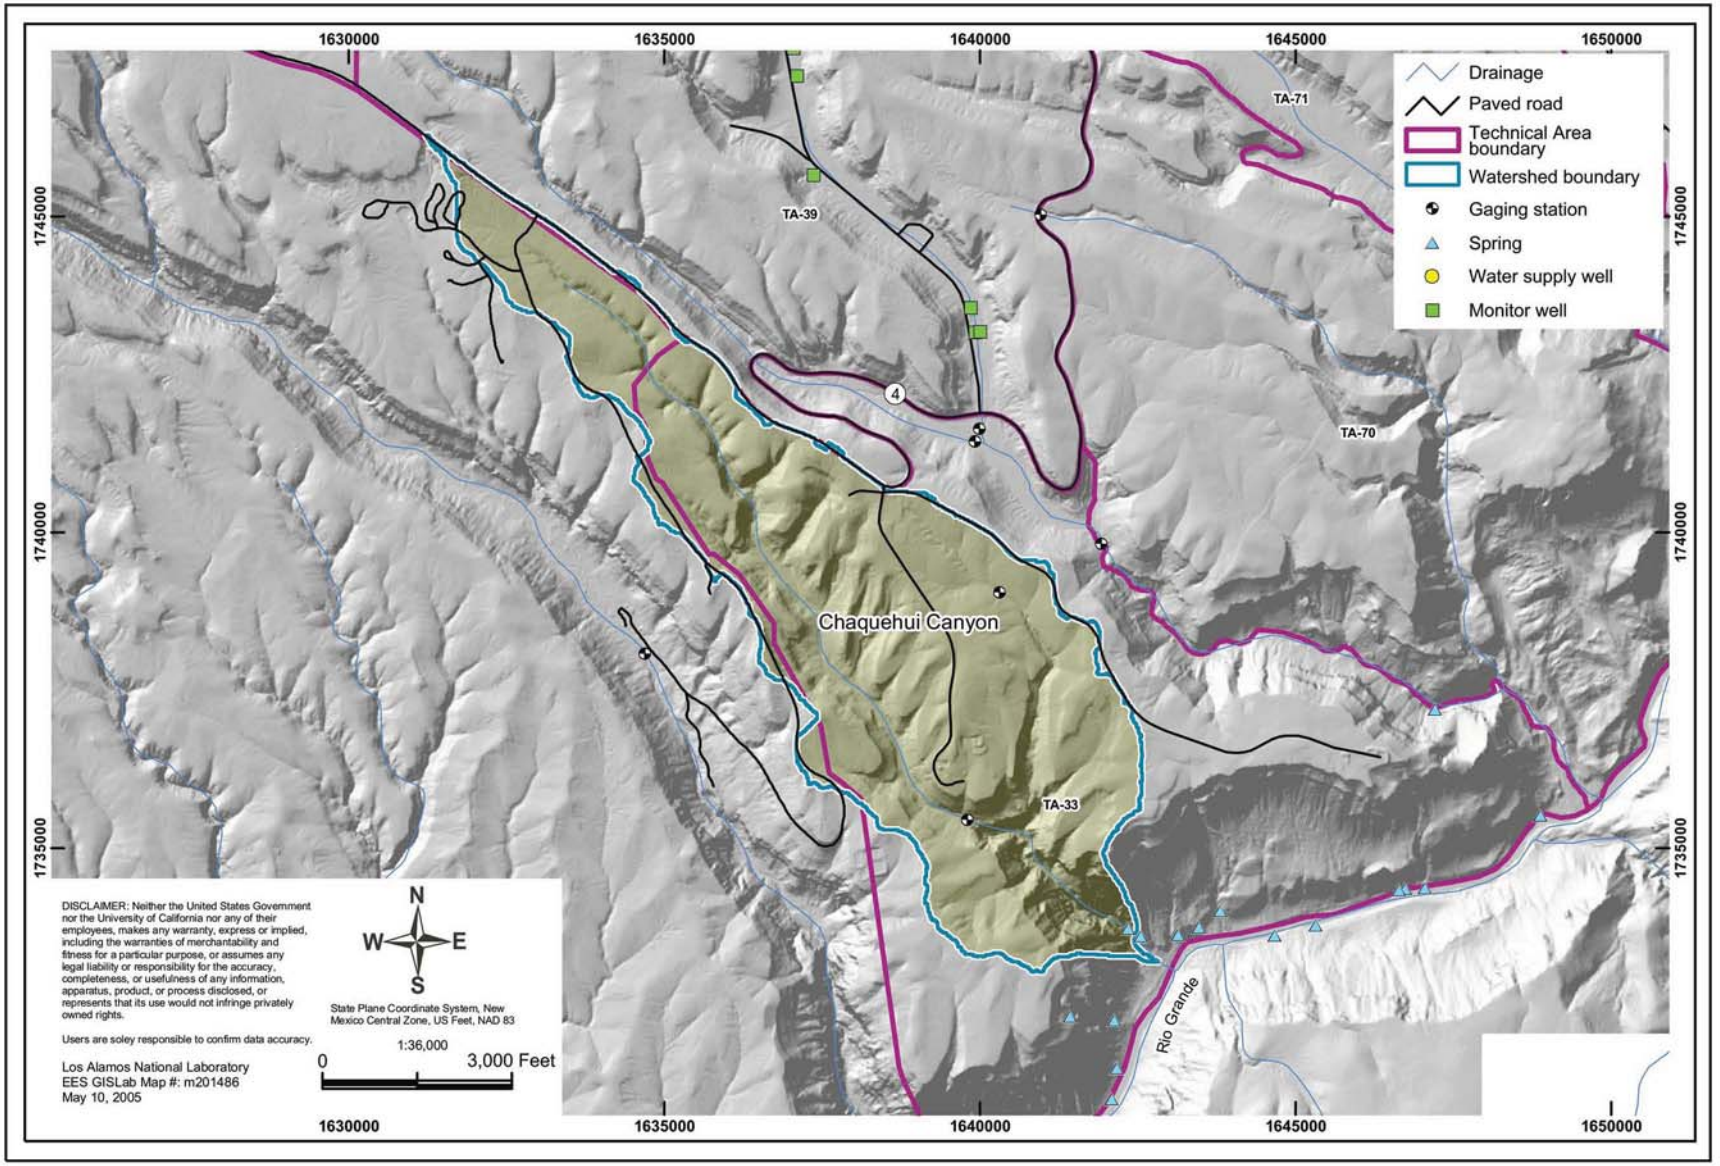

Figure 3-A-8. Ancho Canyon watershed.

Table 3-A-8.
Chaquehui Canyon Watershed Description

Hydrogeologic Element	Characteristic	Description
Surface Water	Flow	Chaquehui Canyon heads on the Pajarito Plateau and has a drainage area of about 2 square miles. It contains an ephemeral stream in its upper portion (Figure 3-A-1, Figure 3-A-9).
	Quality	
Springs	Name	Springs issue from basalts near the Rio Grande in the area of Chaquehui Canyon (Springs 8A, 9, 9A, 9B, and Doe Spring). These springs are located 130-200 ft above the Rio Grande. About 0.5 mile above the Rio Grande, Doe Spring, a regional aquifer spring, maintains a short perennial reach. Farther down the drainage, Springs 9, 9A and 9B maintain perennial flow that extends 0.25 mile to the Rio Grande.
	Quality	
Alluvial Groundwater	Extent	Little is known about the presence of alluvial groundwater in Chaquehui Canyon. Much of Chaquehui Canyon is unlikely to contain perched alluvial groundwater because most of its course forms a steep narrow drainage through basalts that are swept free of alluvium by runoff. Purtymun reported that there was water perched locally in the alluvium but provided no basis for this statement. Purtymun probably refers to alluvium downstream of Doe Spring and Springs 9 and 9A.
	Depth/Thickness	See above.
	Quality	See above.
Intermediate Groundwater	Extent/Hydrology	No intermediate groundwater is known in Chaquehui Canyon; however there has been no drilling in the area.
	Depth/Thickness	See above.
	Quality	See above.
Regional Aquifer	Depth/Hydrology	The springs may represent discharge from the regional aquifer in White Rock Canyon. Well R-31 in TA-39 (Ancho Canyon) found the regional aquifer at about 530 ft within the Cerros del Rio basalt, the underlying Puye Fanglomerate, and “Totavi” gravels.
	Quality	
Contaminants	Potential Sources	Chaquehui Canyon lies south of the mesa occupied by TA-33. TA-33 was used as a firing site and for production of tritium. PRSs include landfills, septic systems, and burn areas. TA-33 is situated on a mesa top and is being investigated by the ER Project as Operable Unit (OU) 1122.
	Type

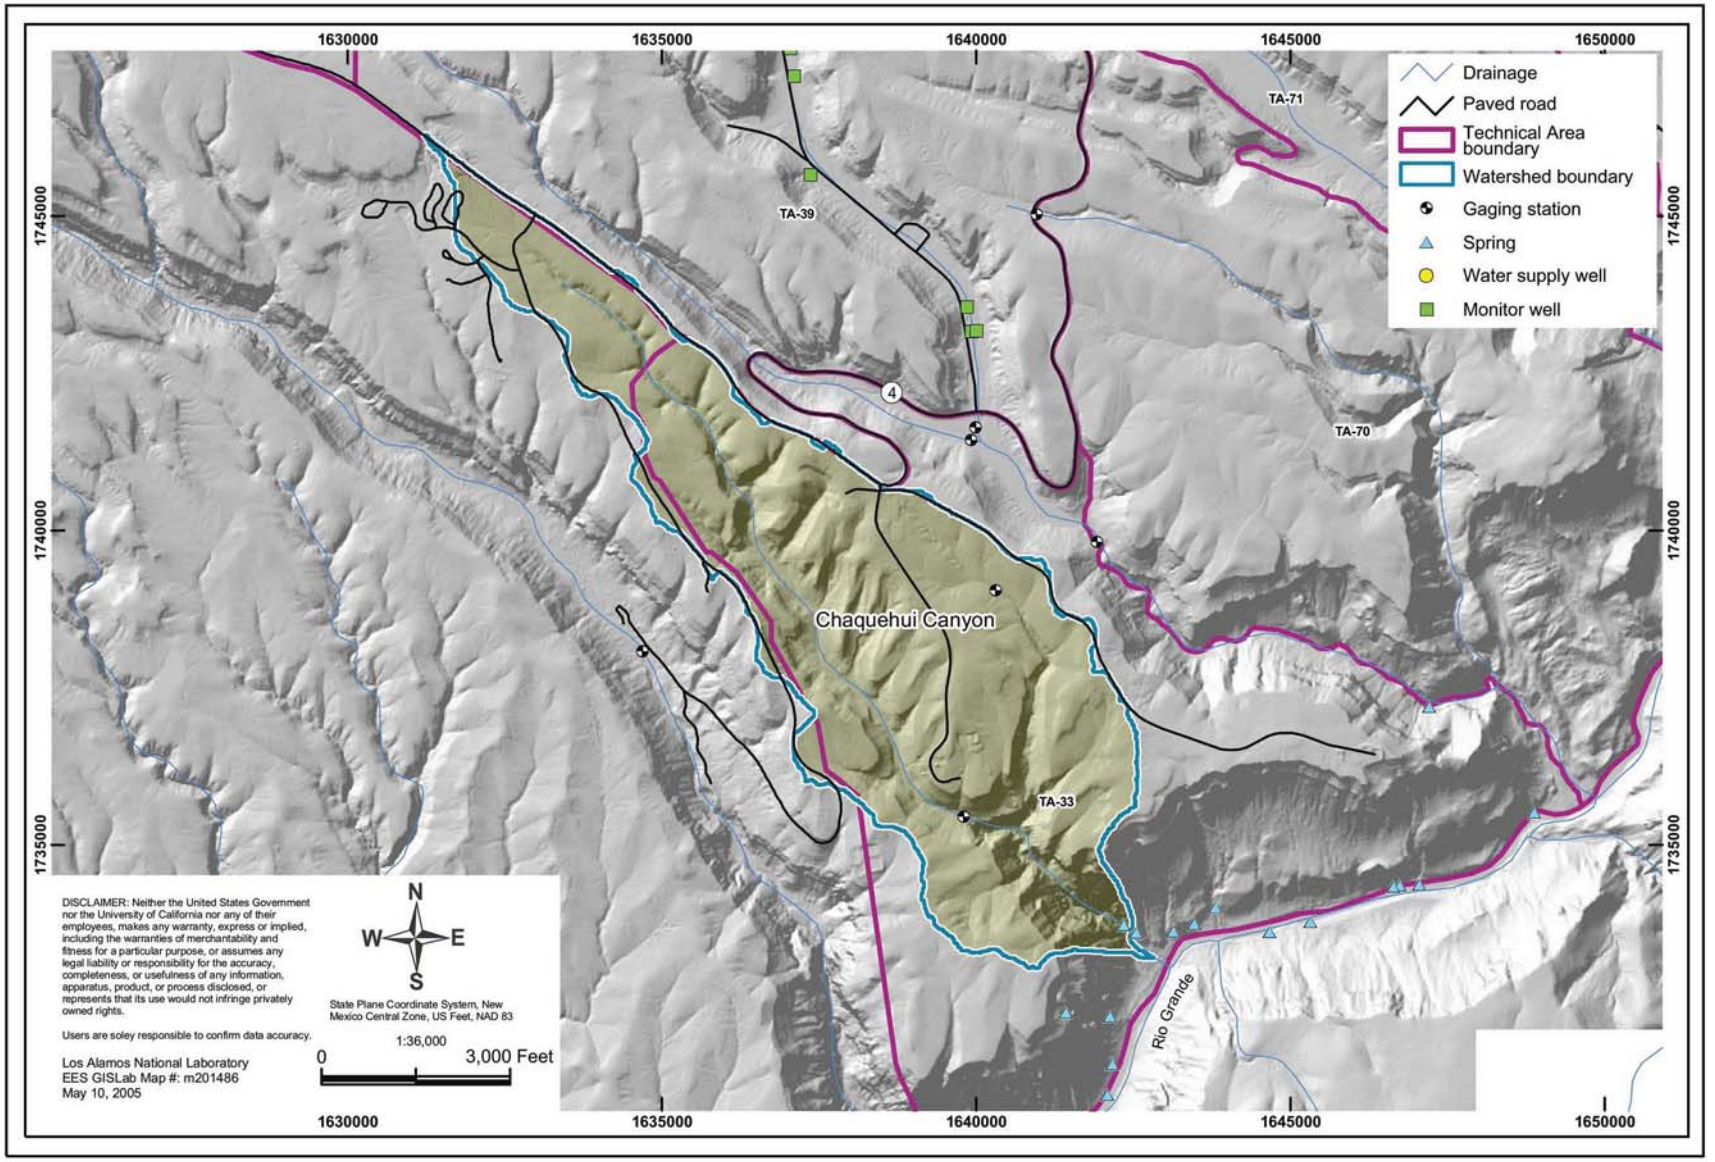

Figure 3-A-9. Chaquehui Canyon watershed.

Table 3-A-9.
Frijoles Canyon Watershed Description

Hydrogeologic Element	Characteristic	Description
Surface Water	Flow	Frijoles Canyon lies on US Forest Service and US Park Service lands south of Laboratory land and heads within the Sierra de los Valles (Figure 3-A-1; Figure 3-A-10) with a drainage area of about 19 square miles. Rito de los Frijoles is a perennial stream that originates in the upper canyon and extends to the Rio Grande.
	Quality	The Laboratory has monitored surface water quality at two locations for several decades, one near the park headquarters and one just above the Rio Grande. In general, no Laboratory-derived contamination has been observed. The National Park Service has monitored surface water quality extensively in Frijoles Canyon. High fecal coliform bacteria counts originating from local sanitary sources and horse corrals have been a major issue in surface water quality.
Springs	Name	Rito de los Frijoles originates from springs in upper Frijoles Canyon. One regional aquifer spring, Spring 10, discharges at the edge of the Rio Grande south of Frijoles stream. The spring has a very low discharge and is difficult to sample separately from adjacent river water.
	Quality	
Alluvial Groundwater	Extent	No wells have been drilled into the alluvium in Frijoles Canyon. The presence of perennial surface flow suggests a large extent of alluvial saturation.
	Depth/Thickness	The alluvium is probably thin, on the order of 6 m or less.
	Quality	See above.
Intermediate Groundwater	Extent/Hydrology	No intermediate groundwater is known to exist in the area of Frijoles Canyon; however no wells have been drilled.
	Depth/Thickness	See above.
	Quality	See above.
Regional Aquifer	Depth/Hydrology	No regional aquifer wells are located in Bandelier National Monument. The nearest wells are in Ancho Canyon.
	Quality	See above.
Contaminants	Potential Sources	Frijoles Canyon lies south of the Laboratory boundary near the Rio Grande, but is separated from TA-33 by Chaquehui Canyon. Local sanitary sources and horse corrals have been potential source of contamination.
	Type	There is a high fecal coliform bacteria count in surface water.

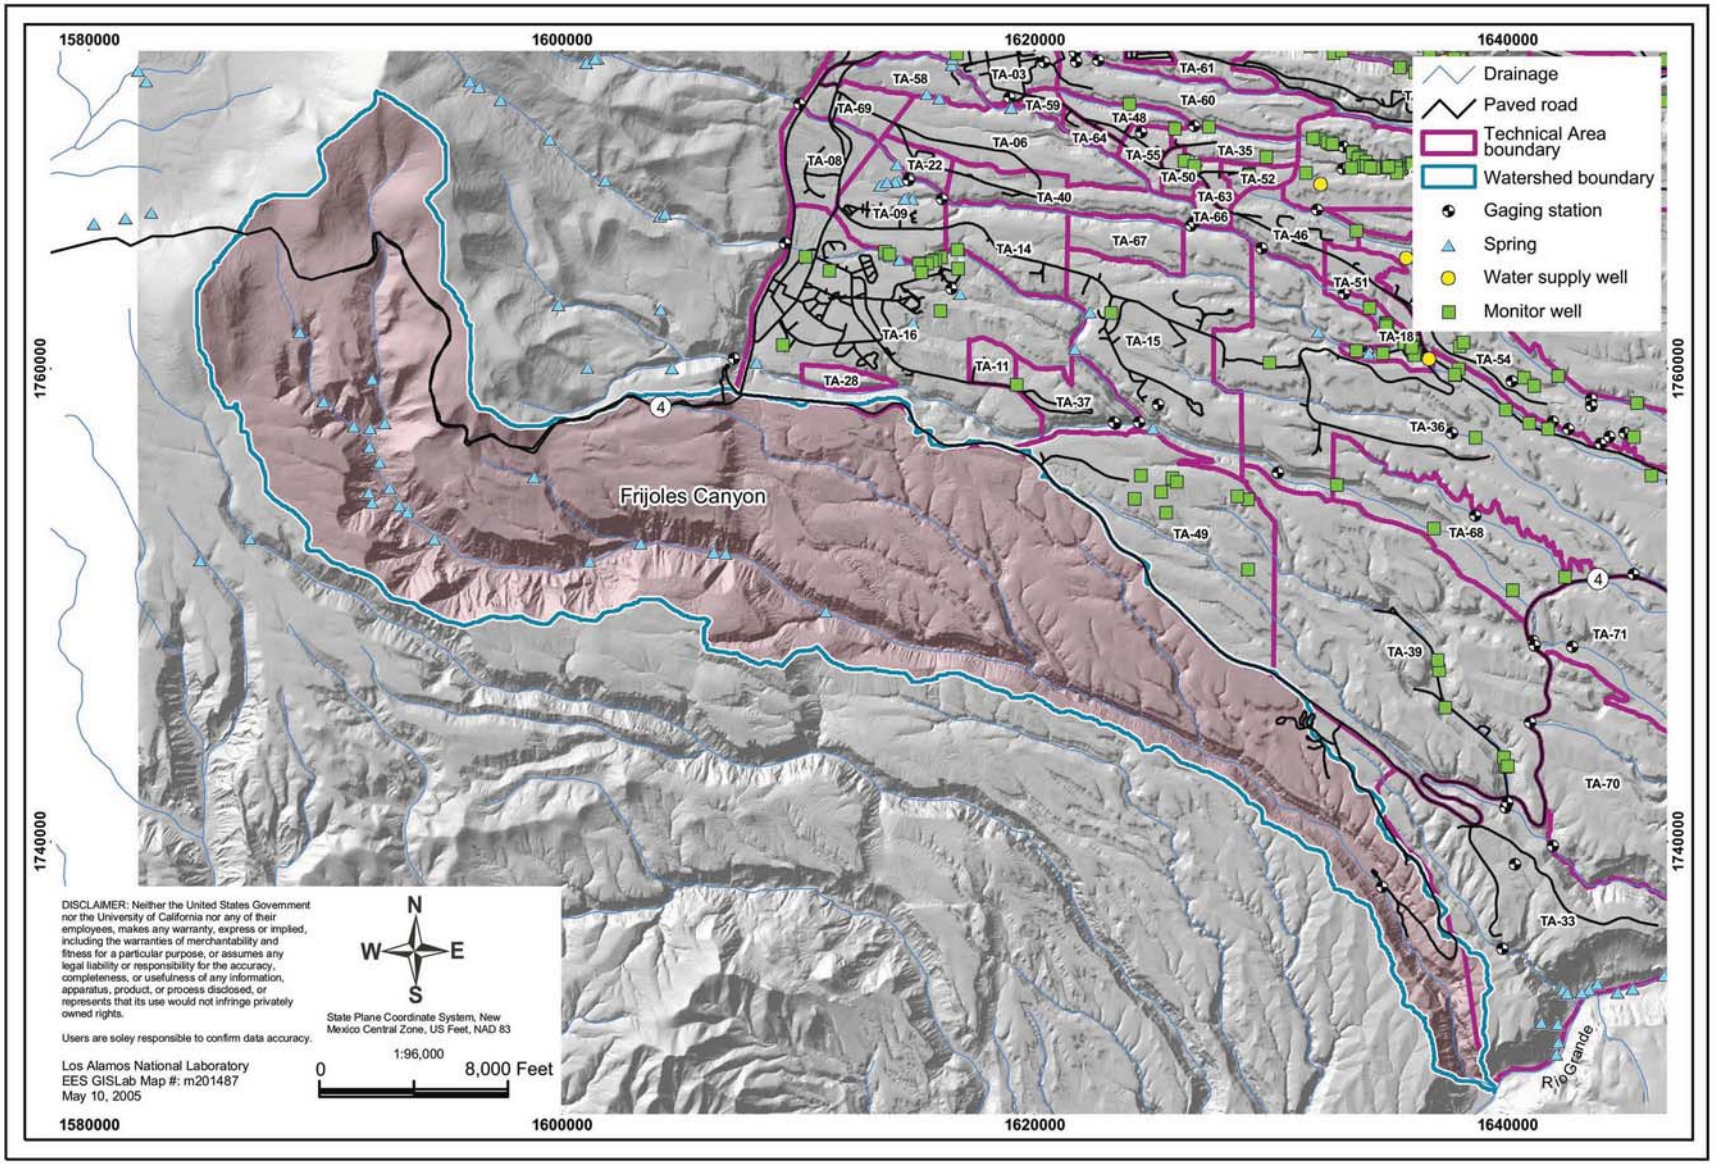

Figure 3-A-10. Frijoles Canyon watershed.

Table 3-A-10.
White Rock Canyon Watershed Description

Hydrogeologic Element	Characteristic	Description
Surface Water	Flow	Flow from regional aquifer springs supports perennial surface water flow in several canyons just above where they reach the Rio Grande: Sandia, Pajarito, Ancho, and Chaquehui canyons (Figure 3-A-1, Figure 3-A-11). Except for Sandia Canyon, these flows reach the Rio Grande. The Los Alamos County White Rock Sewage Treatment Plant discharges effluent into Mortandad Canyon just above the river at the northern county boundary.
	Quality	The discharge from the White Rock Sewage Treatment Plant is the primary surface water source and has a strong impact on the chemistry of the water that enters the Rio Grande from Mortandad Canyon, leading to higher TDS, nitrate, chloride, sulfate, and some metals. Water quality of the other streams is mainly determined by chemistry of their contributing springs (summarized in the regional aquifer description below). Purtymun (1995) and Purtymun et al. (1980) summarize flow and water quality from the White Rock Canyon springs and surface water.

Table 3-A-10.
White Rock Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Description
Springs	Name	Springs near the Rio Grande represent natural discharge from the regional aquifer. The springs discharge from two geologic units, the Tesuque Formation and the Totavi Lentil (the lower part of the Puye Formation). The Tesuque Formation consists of sandstones, siltstones, and interbedded basalts. The Totavi Lentil is a channel fill deposit made up of grain sizes ranging from gravel to boulders. Most of the springs discharge close to the elevation of the Rio Grande, though some springs discharge at elevations several tens of feet above the Rio Grande. The springs can be divided into four groups: **Group I springs** discharge from the Totavi Lentil on the west side of the river. The spring water is dominated by calcium bicarbonate with sulfate and chloride of about 4 mg/L and TDS averages 163 mg/L. **Group II springs** discharge from coarse-grained Tesuque Formation sediments on both sides of the river. These springs have sodium bicarbonate water with about 3 mg/L of sulfate and chloride, and TDS averages 183 mg/L. **Group III springs** discharge from fine-grained Tesuque Formation sediments on the west side of the river. These springs also have sodium bicarbonate water with about 10 mg/L of sulfate, 3 mg/L of chloride and TDS averages 215 mg/L. **Group IV springs** discharge from fine-grained Tesuque Formation sediments on the east side of the river near faults and basalt flows. These springs have varied chemistry with higher TDS than the other springs, of 270 to 500 mg/L. The springs discharging from the Totavi Lentil (Group I springs) follow the outcrop of this formation, increasing their elevation above the river in a downstream direction. These higher elevation springs generally occur on the flanks of or in the bottom of canyons where erosion has exposed the Totavi Lentil. The elevation of springs above the river could reflect channeling of discharge from the regional aquifer along the higher-permeability Totavi Lentil, combined with the increase in elevation of the water table with distance west of the river. An alternative hypothesis about spring origin is that the elevation of some springs (Spring 4A) above the river indicates that they discharge from perched groundwater located above the regional aquifer. As well, the elevation of springs above the river could reflect complex flow paths resulting from local variations in geology and permeability related to numerous large-scale landslides along the canyon walls.
	Quality	The US Geological Survey and the Laboratory have monitored chemistry of the White Rock Springs since the 1960s; the springs show no clear impact of Laboratory contamination. Tritium values in the springs are either in the range of regional aquifer values, namely less than 3 pCi/L, or up to 40 pCi/L, which could indicate either Laboratory impact or a component of precipitation. A few springs have relatively high natural uranium. These springs lie mainly on the east side of the river

Table 3-A-10.
White Rock Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Description
		near and north of the Buckman wellfield. Some springs (1, 3, 3A, 4, 5) also show subtle increases in nitrate over 20 years. These increases could be due to the impact of feral cattle grazing near the springs over time as well as to some change in groundwater quality. Perchlorate has been measured at low levels in some springs, but the source is not clear.
Alluvial Groundwater	Extent	Alluvial groundwater is not present in the White Rock Canyon area. However, household wells in Los Alamos Canyon (Halladay and Otowi) and household wells nearer the Rio Grande probably draw their water from Santa Fe Group sediments but may draw water in part from alluvium in these drainages.
	Depth/Thickness	See above.
	Quality	See above.
Intermediate Groundwater	Extent/Hydrology	Perched intermediate groundwater may not be present in the White Rock Canyon area. However, an alternative hypothesis about White Rock Canyon spring origin is that the elevation of some springs above the river indicates that they discharge from perched groundwater located above the regional aquifer.
	Depth/Thickness	See above.
	Quality	See above.
Regional Aquifer	Depth/Hydrology	The Rio Grande is the major groundwater discharge zone for the regional aquifer underlying the Pajarito Plateau. The river gains flow through White Rock Canyon, indicating that the local water table (the regional aquifer) lies above the river. The City of Santa Fe operates the Buckman wellfield on the east side of the Rio Grande across from White Rock (Figure 3-A-11). The wellfield includes eight pumping wells. These wells draw their water from Santa Fe Group sediments. Vesselinov and Keating (2002) concluded from a modeling study that under long-term steady state conditions, these wells might one day draw perhaps a third of their water from beneath LANL on the west side of the Rio Grande. As a result, LANL has sampled three of the Buckman wells (1, 2, and 8) since 2001 for its Environmental Surveillance Program. Water in these wells is quite old, having passed through the deeper portion of the basin fill sediments where it acquired a higher load of dissolved solutes. San Ildefonso Pueblo draws water from more than 10 community and household wells located on both sides of the Rio Grande. Little information on depth or geology for these wells is available. Many of these wells probably draw their water from Santa Fe Group sediments. At least two of the San Ildefonso wells are uncapped artesian wells.
	Quality	The US Geological Survey and the Laboratory have monitored chemistry of the White Rock Springs since the 1960s; the springs do not show a definitive impact of Laboratory contamination. Tritium activities in the springs are either in the range

Table 3-A-10.
White Rock Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Description
		of regional aquifer values, namely less than 3 pCi/L, or range from 10 to 50 pCi/L, which could indicate either Laboratory impact or a component of local precipitation—more likely the latter given spring locations. A few springs have relatively high natural uranium. These springs lie mainly on the east side of the river near and north of the Buckman well field. Some springs (1, 3, 3A, 4, 5) also show subtle increases in nitrate over 20 years. These increases could be due to the impact of feral cattle grazing near the springs over time, natural source, and seepage from impoundments within Pajarito Canyon and past effluents released in several canyons. Perchlorate has been measured at low levels in some springs, but the source is not clear. The measured perchlorate values are similar to those found in wells distant from LANL. Spring 2B below and east of the White Rock Overlook shows higher concentrations of uranium, chloride, boron, and nitrate than other springs. This spring's chemistry (except for uranium) is similar to the nearby stream in Mortandad Canyon, which is fed by effluent from the White Rock sanitary treatment plant. This similarity in chemistry, along with nitrogen isotope results that indicate a sewage source for both waters, suggests that a large part of the water from Spring 2B comes from the treatment plant effluent in lower Mortandad Canyon. It is possible that natural uranium within the Santa Fe Group sediments has been leached from mineral surfaces in contact with the bicarbonate-rich groundwater. Increasing concentrations of carbonate alkalinity are from the treated sewage effluent discharged upgradient from the spring. Some Buckman wells have exceptionally high uranium (up to 230 ppb, compared to the new EPA MCL of 30 ppb). Such naturally occurring uranium is common in the Pojoaque and Tesuque area. The Buckman wells also have high sodium, carbonate alkalinity, and TDS.
Contaminants	Potential Sources	TA-33 borders the Rio Grande at the southern end of LANL along White Rock Canyon. The RFI Workplan for OU 1122 describes environmental concerns at TA-33. To the north of TA-33 lies TA-70, a buffer area where no Laboratory activities have occurred. Adjoining TA-70 to the north, Los Alamos County land comprises the low to moderate-density residential area of White Rock. Los Alamos County formerly operated sanitary effluent lagoons near the edge of the canyon just south of Pajarito Canyon. A municipal sanitary treatment plant discharges effluent into Mortandad Canyon just above the river at the northern county boundary. This discharge is the main surface water source and has a strong impact on the chemistry of the water that enters the Rio Grande from Mortandad Canyon, leading to higher concentrations of TDS, nitrate, chloride, sulfate, and some metals. To the north of White Rock is undeveloped San Ildefonso property.

Table 3-A-10.
White Rock Canyon Watershed Description (continued)

Hydrogeologic Element	Characteristic	Description
		Los Alamos Canyon lies at the northern end of White Rock Canyon. LANL effluents have moved down Los Alamos Canyon either adsorbed onto sediments or dissolved in stream flow, affecting sediment and shallow groundwater quality in the lower portion of the canyon (Section 2.4).
	Type	TA-33 was used as a firing site and for production of tritium. PRSs include landfills, septic systems, and burn areas. It is situated on a mesa top and is being investigated by the ER Project as Operable Unit (OU) 1122. If contaminants are released from TA-33, they may impact Ancho Canyon, Chaquehui Canyon, or the Rio Grande. The discharge from the municipal treatment plant is the primary surface water source and has a strong impact on the chemistry of the water that enters the Rio Grande from Mortandad Canyon, leading to higher levels of TDS, nitrate, chloride, sulfate, and some metals.

3-B. Alternative Conceptual Models of Contaminant Transport

The purpose of this section is to discuss two alternative interpretations of how water flows and contaminants behave on the Pajarito Plateau. With the uncertainty that is inherent to all subsurface investigations, it is important to examine the strengths and weaknesses of other possible interpretations of the available data. This section explores alternative conceptual models by first providing a description of the alternative model. Second the strengths and limitations of the alternative are summarized. An assessment of how the alternative conceptual model would change the current conceptual model or how risk is assessed is presented. Finally, a discussion of how the alternative conceptual model could be tested is provided.

3-B-1. Colloid-Facilitated Transport

The movement of small particles in groundwater flow systems can represent an alternate mechanism for contaminant transport. While generally not as significant overall as the movement of dissolved or immiscible species, the movement of small particles can increase the magnitude of mass transport. This section will focus on colloids, a special class of particles with properties the lie between that of the dissolved state and the solid state.

Historically, researchers have applied the term colloid to particles with a size range of 0.001 to 1 micron (1 micron is 0.001 millimeter). The colloids can be mineral particles, particulate organic matter, biological (for example, bacteria), or even microemulsions of hydrocarbons. The surface area per unit mass is very high for colloids, which greatly affects their mass transport. Contaminants can be transported as colloids resulting in unexpected mobility. This is because the transport of contaminants adsorbed to colloids is determined by the physical/chemical properties of the colloid, rather than properties of the contaminant. Work at the Nevada Test Site suggests that plutonium can be transported over significant lateral distances (~1.3 km) by colloids (Kersting et al. 1999). Predicting colloid transport is extremely difficult, however. Colloid stability and filtration depends on a complex array of factors including density, size, surface chemistry, water chemistry, water flow rates, and pore size distribution of the soil matrix. Table 3-B-1 discusses strengths and weaknesses of a colloid-facilitated transport model.

3-B-1.1 Strengths and Limitations of the Colloid-Facilitated Transport Model

Table 3-B-1.
Colloid-Facilitated Alternative Transport Model

Strengths	Limitations
Since the start of discharges in May 1963, the RLWTF has used the flocculate "calcium hydroxide" and "ferric sulfate" as a part of the treatment process, and it is likely that a continual stream of residual colloids was discharged to the canyon floor.	Bulk of radionuclide inventory appears adsorbed to stream sediments.
Work by Penrose et al. (1990) demonstrated the presence of colloids with plutonium and americium along a 3400 m segment of the perched alluvial groundwater system in Mortandad Canyon. The study concluded that the horizontal dispersal of the radionuclides through the groundwater system was due to colloid transport in the subsurface.	That conclusion was challenged, however, by a subsequent review that concluded that the radionuclide transport within the canyon was principally due to surface water, rather than groundwater transport (Marty et al. 1997).
At a mesa top site at TA-21, some of these radionuclides occur at much greater depths in the field than expected. Work by Nyhan et al. (1985) suggests that substantial hydraulic loading can enhance the vertical penetration depth. The study examined the distribution of plutonium, americium-241 and water in Bandelier Tuff beneath former liquid waste disposal sites at TA-21. Nyhan et al. (1985) found that after 17 years of migration, the Am-241 was mobilized under heavy hydraulic loading to 30 m. It is possible that the radionuclides are mobilized by other chemicals or possibly by colloid transport in preferential flow paths.	While colloids have been shown to be abundant in the alluvial groundwater, coring has not shown appreciable vertical movement (less than five feet) of plutonium or americium in the vadose zone below the alluvium (Stoker et al. 1991). Studies show that 99% of the plutonium inventory is adsorbed on alluvium and little is in the water column; the colloidal fraction in groundwater represents less than 1 percent of the total plutonium inventory in the canyon (Purtymun et al. 1984; Stoker et al. 1991). These results suggest that vertical transport of the radiocolloids has been minimal in the Bandelier Tuff beneath the canyon floor, even after decades of continual liquid release.
Occasional Pu-239, -240 detects in samples from water supply wells (1970s and 1980s mostly) may be colloid related.	No plutonium detects in recent years and earlier detections primarily limited to water supply wells---few in monitoring wells. Unable to validate earlier results because of limitations in existing records.

3-B-1.2 Effect on Current Conceptual Model and Assessment of Risk

Many radionuclides and metals are currently conceptualized to be relatively immobile at the site. If colloid-facilitated transport is significant, the subsurface travel times for these constituents to the accessible environment will be reduced. Health risks from colloid-facilitated transport, however, likely will not be greatly different from the levels presently recognized: sampling of the groundwater systems account for the total contaminant concentrations and already include any colloid contributions, if present. Monitoring of the shallower groundwater at the site, the depths where contaminated colloids should be most abundant, has identified few areas with concentrations above a regulatory standard. Given the vadose zone thickness and likely reduction in contaminated colloid concentrations with depth, contaminant concentrations due to colloid-facilitated transport in the regional aquifer are also expected to meet regulatory standards.

3-B-2. Cs-137 "Groundwater Transport" to the Rio Grande

A report written by Norm Buske (2003) for the RadioActivist Campaign (TRAC) and Concerned Citizens for Nuclear Safety (CCNS) in late October 2003 cites samples of aquatic moss from Spring 4A and the Pajarito Stream containing "…consistently low levels of cesium-137 *of LANL* origin [emphasis added]. This is the first confirmed detection of LANL radioactivity from a groundwater pathway." The report also cited moss samples from other sites, as testing positive for Cs-137 and said samples showed Cs-137 "in the range of 0.01 to 6 picocuries/kilogram…Cesium-137…is…at levels far too low to be considered a public health concern." Table 3-B-2 discusses strengths and limitations of a Cs-137 transport model.

3-B-2.1 Strengths and Limitations of Cs-137 Groundwater Transport Alternative Model

Table 3-B-2.
Cs-137 Groundwater Transport Alternative Model

Strengths	Limitations
Detections of tritium and perchlorate in other White Rock Canyon springs support this model.	Levels of these constituents may be within natural ranges. When converted to an equivalent weight basis, the amount of cesium measured by Buske (2003) in the moss samples is within the background concentrations for plants in northern New Mexico.
Cesium-137 is a major Laboratory contaminant in Los Alamos and Mortandad Canyons radioactive effluent discharges.	Cesium-137 is a common fallout radionuclide that was distributed globally during atmospheric nuclear tests. It is considerably more probable that the moss accumulated cesium from worldwide fallout rather than from groundwater. Fallout cesium-137 is universally present in surface soils and soil concentrations are one hundred times greater those found in study.
	The Buske (2003) results were very close to detection levels, in the range of 0.01 to 6 pCi/Kg wet, and the study did not include control samples (upstream) so that Cs-137 from fallout sources could not be compared.
	If Cs-137 traveled through groundwater to a spring along the Rio Grande, several non-adsorbing chemical constituents that usually reflect groundwater contamination, such as nitrate or tritium, likely would accompany and precede Cs-137. Tritium and nitrate values in Spring 4A indicate the spring water reflects background aquifer conditions unaffected by Laboratory discharges.
	From 1995 through 2003, LANL has made 121 Cs-137 measurements in White Rock Canyon springs, with only two detections in the data set. Nine of these measurements (with only one detection) were from Spring 4A. Thus, the body of data does not support the presence of Cs-137 in any White Rock spring, at an average detection limit of 3 pCi/L. In addition, Cs-137 is not detectable in regional aquifer monitoring wells upgradient of the springs.

3-B-2.2 Effect on Current Conceptual Model and Assessment of Risk

If real, the groundwater transport of Cs-137 alternative conceptual model would indicate that relatively immobile radionuclides or metals may potentially move through groundwater to the accessible environment at a faster rate than recognized. Assessment of water quality changes at those locations would continue in the future. The current monitoring results from across the regional aquifer do not indicate any location where the concentrations of these constituents are greater than regulatory standards. Given this pattern, it is highly unlikely that concentrations greater than standards would be observed in the future. Contaminant transport models that only take into account sorption and solubility may underestimate the extent a colloid-bound species is able to migrate in groundwater.

A study is being conducted by a LANL team to assess the distribution and concentrations of cesium in moss throughout northern New Mexico. The objective is to collect various moss sample specimens from springs located in northern New Mexico and southern Colorado (a great distance from LANL) and analyze them for Cs-137 activity. This program will collect the data necessary to evaluate whether Cs-137 concentrations near the Laboratory are anomalous. Additional monitoring of wells and springs in the Los Alamos area will continue to look for evidence of rapid movement of cesium (and other contaminants) through the groundwater system.

APPENDIX 4-A. METHOD FOR ESTIMATING INFILTRATION RATE IN CANYONS

Net infiltration is defined as the flux of water that percolates to depths greater than the zone in which evapotranspiration (ET) processes take place. A complete site-wide study of net infiltration has recently been completed (Kwicklis et al. 2005). That study presents estimates of net infiltration determinations with a variety of estimation techniques, including Darcy's Law, chloride mass-balance and water-balance methods. The study extrapolates these estimates to other areas within the site for which estimates do not exist. Factors used to make this extrapolation include topography, soil type, vegetation, and bedrock type. The Kwicklis et al. (2005) publication was not ready in time to be used in model predictions presented elsewhere in this report. Previous modeling analyses should be updated to include the detail from the site-wide net infiltration study, as appropriate.

Since net infiltration to the vadose zone beneath the plateau is assumed to occur mainly through canyons, the plateau is differentiated topographically as mesa or canyon. For the net infiltration map presented here, the mesa locations are all assigned the same fixed net infiltration rate. For the base-case study, this rate is 1 mm/yr (Section 2.6.1). More variability is added to the map for canyon locations because the canyons are the main source of recharge across the plateau, and also because conditions in canyons across the plateau vary from wet to dry. For these reasons, a ranking scheme was developed to classify portions of canyons by a net infiltration index (NII) that describes the net infiltration rate.

The net infiltration index ranges in value from one to five, with one representing the lowest and five representing the highest infiltration potential. The NII is based on a number of physical factors, as shown in Table 4-A-1:

- The location of the headwaters is the first factor because those canyons that head in the mountains generally have a larger drainage area, and receive more precipitation and run-off than those that head on the plateau. Anthropogenic water sources within the canyons can also yield large surface flows that contribute similarly to headwaters located higher in the mountains. For this reason, anthropogenic sources were included with the first factor.
- The persistence of surface water in the canyon bottom is the next factor used to define the NII. Those canyons with perennial streams are expected to generate higher net infiltration than those with ephemeral or intermittent streams, and therefore receive a higher ranking.
- Observation of alluvial water is the final factor used to define the NII. Some canyons have alluvial groundwater of significant depth while others have limited or no alluvial water. Those canyons with deeper alluvial groundwaters receive a higher net infiltration index than those without.

Note that the factors contributing to the NII are used to define a set of net infiltration indices that may be updated with site-specific observations and data. However, as a general approach for supporting a plateau-wide modeling effort, the NII is a reasonable simplification. In some cases, factors such as persistent surface and alluvial waters may indicate an absence of vadose-zone infiltration rather than a higher net infiltration rate. Examples of this include the surface expression of springs or perching in the alluvium caused by a large contrast in hydraulic conductivity between the alluvium and underlying tuff. Despite these types of alternative

hypotheses, the model assumes a higher NII in the wetter areas, so that it errs on the side of predicting more rapid transport. Once areas with potential fast paths are identified, more site-specific and detailed net infiltration studies can be performed to refine the predictions.

Table 4-A-1 also includes the net infiltration assumed for each NII. These estimates exhibit approximately three orders of magnitude variation in net infiltration between the driest and the wettest canyons. To assess uncertainty in infiltration, different sets of net infiltration estimates are also included in this study.

Once the NII and the associated infiltration rates for each NII have been defined, the next step is to assign net infiltration indices of canyons or portions of canyons across the Pajarito Plateau. This task was accomplished by compiling information from the LANL Hydrogeologic Workplan about the descriptive factors listed in Table 4-A-1. Major canyons from Guaje Canyon, located north of the laboratory, to Chaquehui Canyon, located south of the laboratory, were characterized with respect to the location of their headwaters, anthropogenic sources, and observations of surface and alluvial waters. In most cases, a particular canyon is split into sections because the hydrologic factors change as one moves down the canyon. The characteristics of these canyons or portions of canyons are shown in Table 4-A-1, along with the resulting net infiltration index for each section. The net infiltration index is determined by comparing the characteristics in Table 4-A-1 to the net infiltration factors in Table 4-A-1.

Figure 4-A-1 shows the resulting NII map for the study area with respect to the LANL boundary. Canyons with no portion of their reach inside the site area, in the gray area of this figure, are not assigned a NII as part of this study because laboratory-derived contaminants are not present in these canyons. Infiltration rates converted from the values in Table 4-A-1 were used as the upper water-flux boundary conditions for the series of one-dimensional vadose-zone flow and particle tracking runs.

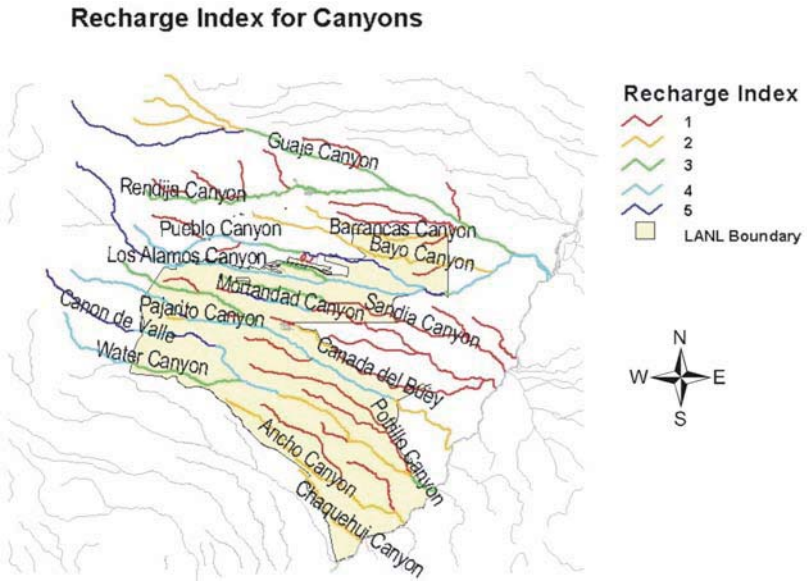

Figure 4-A-1. Infiltration on the Pajarito Plateau: result of analysis to determine the Net Infiltration Index (NII) indicator parameter across the Pajarito Plateau and surrounding region of the study area.

APPENDIX 4-B. MDA G MODEL

This appendix summarizes modeling work previously reported in Birdsell et al. (2000). The purpose of this modeling presentation is to demonstrate the use of the vadose zone concepts outlined in this report and to present representative modeling results for a relatively dry mesa. This system is therefore one end member of the different types of vadose-zone behavior expected for the plateau. A model for the other extreme, a wet canyon, is presented for Los Alamos Canyon in Appendix 4-C.

4-B-1. Introduction and Motivation

Performance assessment (PA) is required to site and authorize permanent disposal facilities for radioactive waste. The purpose of the PA is to demonstrate that performance measures related to protection of human health and the environment are not likely to be exceeded for a specified period of time. Performance objectives and periods of compliance vary according to the characteristics of the radioactive waste being disposed, but groundwater protection for U.S. sites is always explicitly required for at least 1000 years. This study presents an integrated case study that predicts the groundwater pathway dose in support of the performance assessment PA of the active, low-level, solid radioactive waste site located at the Laboratory, shown in Figure 4-4 (from Figure 1 of Birdsell et al. 2000). In contrast to the modeling study of Los Alamos Canyon presented in Appendix 4-C, this model illustrates aqueous contaminant transport from a relatively dry mesa, as opposed to a canyon bottom.

The three-dimensional unsaturated zone flow and transport model captures the complex hydrogeology and topography of the site and yields radionuclide flux estimates to the regional aquifer. Within the unsaturated zone model, the source release of radionuclides is computed for 38 waste disposal pits and four shaft fields (Figure 4-5, from Figure 3 of Birdsell et al. 2000), each contributing to the total inventory. The continued migration of radionuclides through the aquifer is calculated by using a three-dimensional model designed to maintain the temporally and spatially varying distribution of radionuclide flux from the unsaturated zone.

4-B-2. Hydrostratigraphy and Hydraulic Properties

The strata that underlie the LANL waste site are composed of a series of nonwelded to moderately welded rhyolitic ash-flow and ash-fall tuffs underlain by a thin pumice bed (Guaje Pumice), a thick basalt (Cerros del Rio Basalt), and a fanglomerate (Puye Formation), as shown in Figure 4-B-1 (from Figure 3 of Birdsell et al. 2000). The tuff has eroded to leave a system of alternating finger-shaped mesas and canyons. LANL's low-level waste disposal facility is located atop one such mesa with the waste buried in disposal pits and shafts to a depth of approximately 20 m. The surrounding canyons lie 30 m below the steep-sided mesa, and the water table is located approximately 250 to 300 m below the disposal pits.

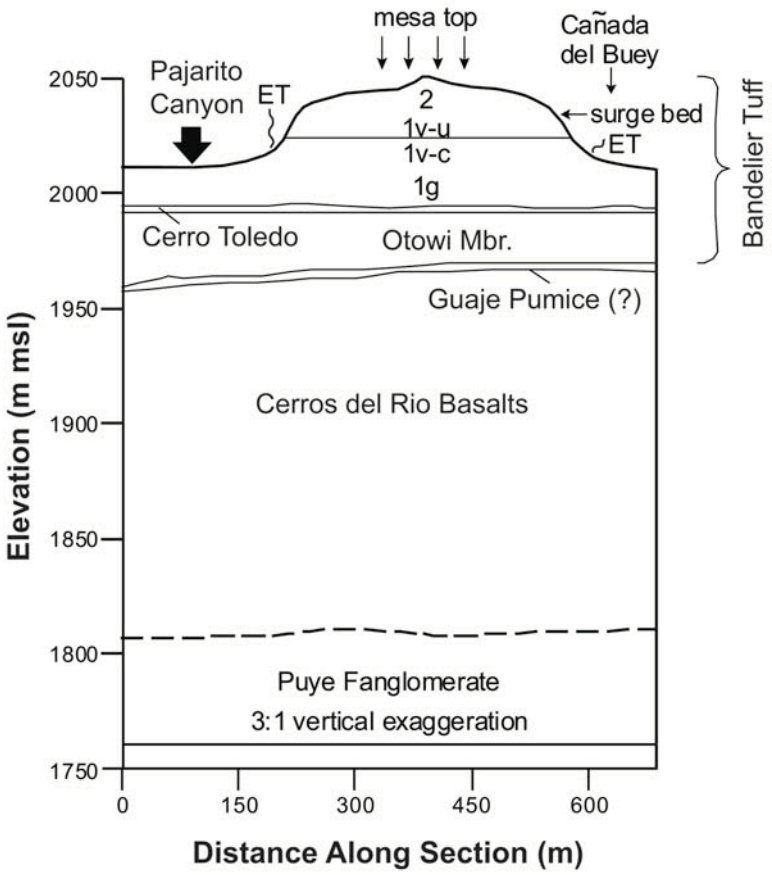

Figure 4-B-1. Conceptual model of hydrostratigraphy of the unsaturated zone for the MDA G Performance Assessment Model.

The stratigraphy at this site has several important features. The Bandelier Tuff, which composes the upper six stratigraphic units (See Figure 4-B-1), dips gently and thins toward the eastern end of the site. The top tuff layer, Unit 2, and the upper few meters of the second layer, Unit 1v-u, are extensively fractured and are separated by a thin surge bed (Krier et al. 1997). Fractures in the deeper tuff units have also been observed in outcrop (Krier et al. 1997). In addition, the Cerros del Rio Basalts, which comprise over 50% of the unsaturated zone, display significant variability (Turin, 1995). The basalts range from extremely dense with no apparent porosity, to highly fractured, to so vesicular as to appear scoriaceous. Finally, the Puye Fanglomerate lies at the base of the unsaturated zone and extends into the saturated zone. The fanglomerate consists of cobbles and boulders of volcanic debris in a matrix of silts, clays, and sands (Purtymun, 1995). Clay, silt and pumice lenses, and interbedded Cerros del Rio basalt are also common.

The van Genuchten model (van Genuchten, 1980), is used to represent the moisture retention characteristic curves for all units in the unsaturated-zone model. Birdsell et al. 2000 summarizes the hydrologic parameters used for all of the units in the unsaturated-zone flow and transport model. The parameters for the van Genuchten model (saturated permeability, porosity, inverse air entry pressure, etc.) are fairly well characterized for the six Bandelier Tuff units and for the crushed-tuff backfill but not for the deeper units. The properties for the tuff units (Krier et al.

1997), the crushed tuff, and the Guaje Pumice were measured on core samples of matrix material. Estimated values for the saturated conductivity and porosity of the Puye Fanglomerate (Purtymun 1984) are used, and we assume that the van Genuchten fitting parameters are similar to those of coarse sands.

No hydrologic property data were available for the basalts at the time this study was performed. The basalt is modeled as a composite-continuum medium made up of both fractures and matrix material (Peters and Klavetter 1988). To ensure conservatism, we set the continuum porosity of the basalt to that of the fractures, thus forcing very low residence times of solutes in this unit for which there was no hydrogeologic characterization data.

4-B-3. Infiltration

Although the average precipitation rate for the area is 35.6 cm/year (Bowen, 1990), most of this precipitation is lost to runoff and evapotranspiration, resulting in a heterogeneous infiltration pattern that is controlled by the mesa/canyon setting of the site. Infiltration is thought to be seasonal with most occurring during spring snowmelt and, to a lesser extent, during the summer thunderstorm season (Rogers et al. 1996a). Figure 4-A-1 shows the different scales of infiltration across the plateau. Based on measured rock saturations and chloride data, a very low net infiltration rate (same as net infiltration, as used in Appendix 4-A) of 1 to 10 mm/year is thought to exist within the mesa. Pajarito Canyon is wetter with an estimated net infiltration rate of 10 to 100 mm/year, while Cañada del Buey is dry with a net infiltration rate similar to the mesa top. The steep mesa sides represent an evaporative region water sink rather than a source region. The coupling of the fractured units separated by the high-permeability surge bed with the mesa's topographic relief is thought to enhance air circulation and consequently lead to evaporative drying within the mesa interior.

4-B-4. Radionuclide Releases

The waste disposal facility occupies about 300,000 m^2 atop a finger-shaped mesa with waste buried in pits and shafts to a depth of approximately 20 m (Figure 4-5). Between 1957 and 1995, solid radioactive waste was buried in 34 disposal pits and in almost 200 shafts located in five shaft fields. The waste form buried at the site contains over 60 radionuclides with the majority of the waste being ^{235}U, ^{238}U, and ^{232}Th. Currently, only low-level radioactive waste is accepted, but prior to 1971, transuranic and mixed wastes were also accepted (Schuman 1997a). An expansion area with four large pits and another shaft field is planned for operation through 2044 and is included in this study.

The waste is categorized in terms of four disposal-unit classifications that are determined by the age of the wastes, because different regulations govern wastes disposed of during different time periods and because inventory records have improved with time. Detailed inventory information for the 1971–1988 waste and the 1988–1995 waste are obtained from disposal records. However, detailed inventory data are not available prior to 1971 and are uncertain for future activities. Therefore, the inventory in the 1957–1970 waste is extrapolated backwards based on disposal operations from 1971 to 1977, and the inventory for the 1996–2044 waste is projected based on current operations and expected future operations (Schuman 1997a; Vold and Shuman 1996).

The release of radionuclides from the disposal units is represented by one of two release mechanisms: rapid release or solubility-limited release (Vold and Schuman 1996). The maximum porewater concentration of each nuclide is calculated based on its inventory, its waste volume and the moisture content in the pits. This concentration is then compared to the nuclide's solubility limit to determine which source-release model is appropriate for each nuclide in each disposal unit. That is, if the maximum porewater concentration exceeds the nuclide's solubility limit, the release concentration is held at the solubility limit until that nuclide's inventory has been exhausted. If the porewater concentration does not exceed the nuclide's solubility limit, the rapid-release model is used. Nuclides with very large solubility limits, such as ^{129}I and ^{99}Tc, are controlled by this mechanism throughout the site.

4-B-5. Computational Grids

The stratigraphic configuration used for the unsaturated zone model is derived from various sources including the then-current LANL site-wide geologic model (Vaniman et al. 1996), well-log picks, and surface observations. The data set is interpolated with the Stratagraphic Geocellular Modeling SGM Software Stratamodel to generate the three-dimensional geologic framework model. The three-dimensional unsaturated zone grid is generated with the Geomesh/X3D software (Gable et al. 1995) from this geologic framework model. An initial grid is constructed with the 45.7-m spacing of the geologic framework model and then resolved to include the 38 waste disposal pits and to better delineate the mesa sides. The final grid contains 41,542 nodes and 254,614 tetrahedral elements.

The saturated zone model extends from just west of the site to the Rio Grande. The grid is rectangular and oriented perpendicular to groundwater equipotentials. It is 9773 m long, 1280 m wide, and 100 m deep with 19,580 nodes and 102,960 tetrahedral elements. To better model the vertical dispersion of the contaminant plumes entering the aquifer from the unsaturated zone, the vertical element height is refined near the water table. The grid is also refined horizontally beneath the site to approximately 500 m downstream to accurately capture the spatial distribution of the radionuclides as they move toward the downstream compliance regions.

4-B-6. Model Implementation

Model implementation issues include how to assign the flow boundary conditions, initial conditions for transient flow, and hydraulic parameters in the model. We will also discuss some assumptions employed in model implementation.

To determine appropriate infiltration rates for the site, Birdsell et al. (2000) ran 5 two-dimensional simulations using different steady mesa-top infiltration rates of 10 mm/year, 1 mm/year, 0.1 mm/year, 0.01 mm/year and 0.0 mm/year, and compared the simulated saturation profiles to site field data. Figure 4-B-2 (adapted from Figure 5 of Birdsell et al. 2000) shows the calculated steady-state saturation profiles at the center of the mesa for the five infiltration rates along with the ranges of in situ saturation data measured in the six Bandelier Tuff units. The shape of the calculated saturation profiles shows the same trend as the data, e.g. saturations

decrease from Unit 2 to Unit 1v-u and then increase again in Unit 1v-c, etc., but no single infiltration rate yields predicted saturation values that fit the entire data set. Based on their study, together with that of Newman (1996), Birdsell et al. (2000) used a range of mesa-top infiltration rates from 1 to 10 mm/year. The bottom boundary for the unsaturated zone model is the water table.

For the saturated-zone model, a steady flow field is calculated by applying a pressure head difference of 101 m (Purtymun 1995) across the east and west sides of the model. No-flow boundaries are used for the top, bottom, north and south sides. Recharge is believed to occur mainly to the west of the site, at higher elevations in the Jemez Mountains. A water-balance estimate shows that the volume of water entering the aquifer from the unsaturated zone at the site is negligible compared to the aquifer volume (Birdsell et al. 1999). Thus, water flowing from the unsaturated zone to the aquifer is not included.

Several assumptions have been made in implementing the simulation model, including steady infiltration rates and an equivalent continuum medium for the Cerros del Rio Basalts. Although the deep percolation is thought to be seasonal with most occurring during spring snow melt and to a lesser extent during the summer thunderstorm season (Rogers et al. 1996a), Birdsell et al. (1999) studied the effects of annual transients in percolation rate on unsaturated zone transport at the site. They found that simulated transient pulses are damped with depth so that the calculated cumulative contaminant flux at the base of the Bandelier Tuff is similar under transient and steady flow fields.

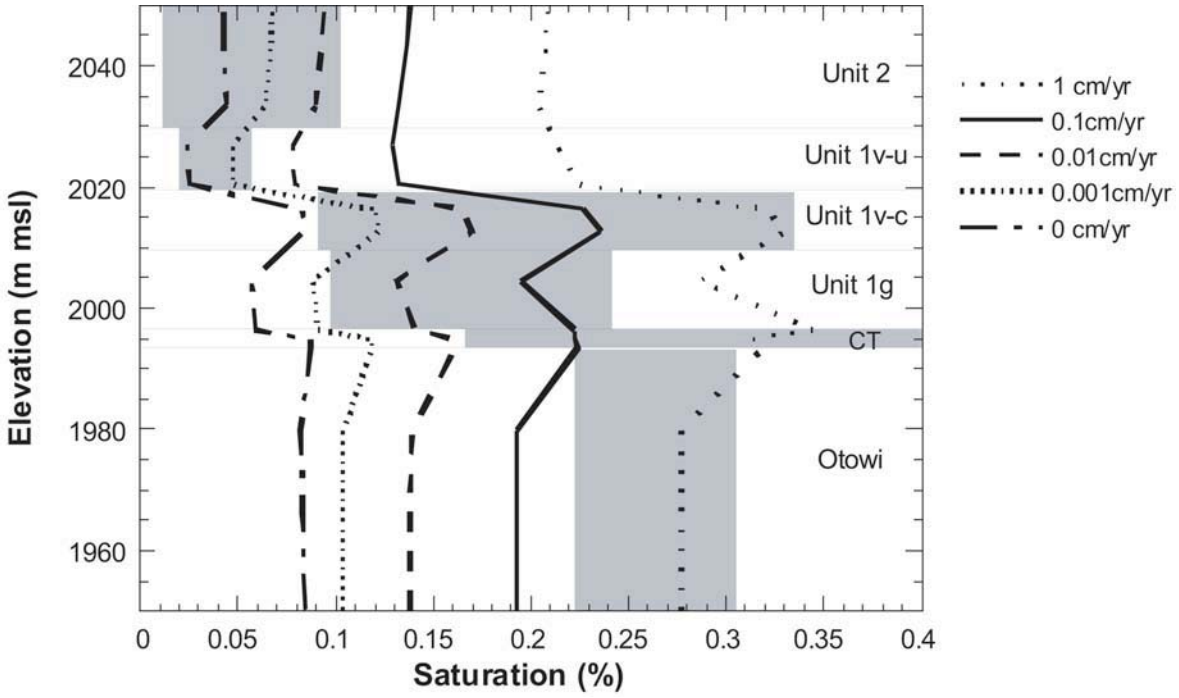

Figure 4-B-2. Comparison of site data (gray boxes) to calculated steady-state saturation profiles for several infiltration rates.

Another important assumption is that matrix flow dominates in the unsaturated tuff units at the site. This assumption is justified by considering that the pits are excavated completely through Unit 2, the most highly fractured tuff unit, thus excluding the fracture system and the likelihood of fracture flow through this unit. In addition, numerical studies of fracture flow for the site indicate that flow through fractured tuffs is difficult to maintain in low-saturation, high-capillarity systems (Soll and Birdsell 1998). Because the site in this study is a solid waste site, significant fracture flow through the unsaturated tuff units is unlikely.

Furthermore, the basalt is modeled as an equivalent continuum medium made up of both fractures and matrix material (Peters and Klavetter1988). Matrix properties are derived from analog basalts in Idaho (Bishop 1991). Fracture properties are chosen, through numerical sensitivity studies, so that no lateral diversion occurs at the top of the basalts in the simulations, even when the flow rate exceeds the matrix saturated hydraulic conductivity. The continuum porosity is set equal to the fracture volume fraction, 10^{-4}, to ensure rapid transport of 1 to 5 years through this unit, hence, foregoing any retardation due to matrix flow or sorption. Notice that this treatment of transport through the basalt yields a conservative result e.g., faster groundwater travel times and higher peak doses than actually expected.

It is evident that there is significant uncertainty in infiltration rates. For the purpose of sensitivity analyses, we defined a base-case set of infiltration rates as a reference, as listed in Table 4-B-1. Variations are made on the base-case infiltration rates to examine the impact of uncertain parameters on the model results.

4-B-7. Representative Transport Result

Unsaturated zone transport calculations were run for ^{14}C, ^{129}I, ^{237}Np, ^{99}Tc, and ^{238}U using the base-case, steady flow field, 5_1_50 (nomenclature for these model results is defined in Table 4-B-1). These nuclides were chosen because of their low distribution coefficients, ranging from 0 to 2.43 for most of the unsaturated zone units. Using screening techniques developed by Birdsell et al. (1995), Birdsell et al. (2000) chose ^{14}C, ^{129}I, and ^{99}Tc, and eliminated the remaining nuclides from consideration in the dose assessment.

Figure 4-B-3 (adapted from Figure 8 of Birdsell et al. 2000) shows the simulated ^{129}I plumes in the unsaturated zone for the four age-dependent waste classes after 1000 years using the base-case flow field. Although the infiltration rate at each source region is the same (5 mm/year), the four plumes are quite different due to both inventory variations and differences in bed thickness. The inventory distribution in the disposal units is heterogeneous, leading to large variations in radionuclide flux from the disposal units to the unsaturated zone. For example, the 1971–1988 (Figure 4-B-3b) inventory dominates the total site release of ^{129}I to the aquifer at 1000 years. Also, the 1988–1995 shafts located near the southern edge of the mesa (Figure 4-B-3c) concentrate nearly 80% of the 1988–1995 ^{129}I inventory into a small area. This localized inventory produces a predominant plume at the southern portion of the mesa, while the pits to the north and west produce the less concentrated plumes. The location of the basalt unit and the effect on plume migration of the vertical, fracture-dominated flow through this unit is readily visible in these simulations. Once the solutes reach the basalt, they migrate quickly through the unit. In the 1996–2044 waste scenario (Figure 4-B-3d), only the plume's leading edge reaches the basalt after 1000 years because the Bandelier Tuff units are much thicker beneath this proposed expansion area.

To assess the effect of uncertainty in flow rate on transport results, Birdsell et al. (2000) examined the transport of the 1988–1995 ^{129}I inventory using different flow fields and compared the nuclide fluxes through the unsaturated zone. Figure 4-B-4 (from Figure 10 of Birdsell et al. 2000) shows the total flux of ^{129}I for the five flow fields described in Table 4-B-1. By comparing the 1_1_20 case, the 5_1_20 case, and the 10_1_20 case, it is seen that increased mesa percolation leads to faster breakthrough and increased solute flux through the unsaturated zone. This flow-rate dependency is compounded by the velocity-dependent rapid-release source term. The solute flux at 1000 years for the lowest flow case, 1_1_20, is five to seven orders of magnitude less than the other cases considered. This case is used to predict the lower-bound dose in the uncertainty analysis. Comparing the 5_1_20 case to the 5_1_50 case shows that additional flow through Pajarito Canyon results in faster breakthrough and increased solute flux to the saturated zone. The 10_5_100 case represents the wettest case and yields the fastest breakthrough and highest flux to the saturated zone and, consequently, the highest dose over the first 1000 years. This case is used to estimate an upper-bound dose for the uncertainty analysis.

Table 4-B-1.
Infiltration Rates (mm/year) Used as Upper Boundary Conditions for MDA G Performance Assessment

	Mesa Top	Cañada del Buey	Pajarito Canyon
1_1_20 (lowest flow case)	1	1	20
5_1_20	5	1	20
5_1_50 (base case)	5	1	50
10_1_20	5	1	20
10_5_100 (highest flow case)	10	5	100

4-B-8. Discussion

Due to uncertainty in model parameters, the results of these transport simulations contain intrinsic uncertainty. The greatest uncertainties associated with predicting aquifer-related doses from the site, according to Birdsell et al. (2000), are related to the understanding of the mechanisms that control flow and transport within the unsaturated zone and our ability to model these mechanisms. At this point, they concluded that uncertainty related to the hydrologic processes themselves, i.e., conceptual model uncertainty, dominates the ability to make accurate predictions of transport at the site moreso than uncertainty related to the hydrologic and geochemical properties data. Importantly, however, predicted doses using parameters from the most conservative ends of the uncertain ranges are still well below regulatory concern.

The results of Birdsell et al. (2000) indicate that the mesa-top infiltration rate has the greatest impact on the simulated migration of waste through the unsaturated zone. It controls both the source release rate and subsequent downward solute migration. They bounded this uncertainty by considering a base-case flow field and high- and low-flow cases. As shown in Table 4-B-2, a variation in mesa-top infiltration rate from 1 to 10 mm/year results in a range of six orders of magnitude in the 1000-year groundwater-related doses. Clearly, a good understanding of this key parameter is important to the dose assessment. However, because doses are so much less than the performance objectives developed in Birdsell et al. (2000), conservative yet realistic infiltration rates seem adequate for this site. With respect to travel times, models of dry mesas such as that

associated with MDA G generally predict travel times in the neighborhood of 1000 years or more. This basic result indicates that groundwater pathway risks associated with waste disposed under dry mesa conditions are expected to be risks that will present themselves far into the future, as opposed to there being a significant present-day risk. This result applies only to the groundwater: a complete pathway assessment should be conducted that includes other exposure scenarios in addition to groundwater.

Table 4-B-2.
Maximum Ground Water and All Pathways Doses for the PA and CA Wastes, Base Case Flow Field (mrem/yr) MDA G Performance Assessment.

	PA - Ground Water	PA - All Pathways	CA - All Pathways
Performance Objective	4	25	100
1000 yr (Base Case)	2.4×10^{-7}	6.5×10^{-7}	3.7×10^{-5}
Peak Dose (Base Case)	3×10^{-5} @ ~4500 yrs	1×10^{-4} @ ~4500 yrs	2×10^{-3} @ ~3000 yrs
1000 yr (high-flow case)	8.0×10^{-6}	2.2×10^{-5}	1.4×10^{-3}
1000 yr (low-flow case)	9×10^{-12}	2×10^{-11}	1×10^{-10}

Source: Birdsell et al. (2000).

Finally, there are residual uncertainties related to flow in the deeper unsaturated-zone units for which few hydrologic data are available. The simulations take virtually no credit for transport times through the Cerros del Rio basalts, which make up more than 50% of the unsaturated zone. The transport results are based on the steady-flow assumption and on the use of matrix, hydrologic properties for all tuff units at the site. The response of this fractured system to transient flow events is not completely known. Transient calculations (Birdsell et al. 1999) indicate that the steady-flow assumption is adequate because fluctuations in both saturation and contaminant flux rates dampen with depth even when including fractures in the upper two units. Fracture infiltration studies (Soll and Birdsell, 1998) lead to the conclusion that fracture flow is difficult to initiate and is short-lived in the upper two tuff units at the observed low field saturations. These conclusions are supported by modeling studies presented for Los Alamos Canyon in Appendix 4-C, as well as the findings of Robinson et al. (2005b).

APPENDIX 4-C. LOS ALAMOS CANYON MODEL

4-C-1. Introduction and Motivation

Los Alamos Canyon, as shown in Figure 4-6, is one of the most complex sites at the Laboratory. A number of technical areas have been or are currently located in or adjacent to the canyon, resulting in multiple release locations along the canyon. This section examines, through a synthesis of available data and the development of numerical models, fluid flow and contaminant transport in the vadose zone beneath Los Alamos Canyon. The subsurface hydrology and transport in the vadose zone is also a challenging activity, given the wide range of infiltration rates, the presence of perched water, and the introduction of a host of contaminants of different chemical properties. Because the canyon serves as a collector of a wide range of contaminants, we decided that it was necessary to develop a model at the scale of the canyon, rather than at a smaller scale. The specific goals of the model are as follows:

- Synthesize the available data and conceptual understanding of the vadose zone hydrology beneath Los Alamos Canyon;
- Produce a "base-case" numerical model of the subsurface vadose zone hydrology that ultimately can be used to predict contaminant migration rates and concentrations in fluids reaching the regional aquifer beneath the canyon;
- Quantify the uncertainties associated with those predictions by establishing the bounds on system behavior through a suite of possible models, all of which are consistent with the available data, but which bracket the range of possible behavior;
- Provide a simulation tool for predicting the fate and transport of contaminants in Los Alamos Canyon under different assumed hydrologic and ER stewardship scenarios; and
- Demonstrate a model development methodology that can be used in studies of other canyons on the Pajarito Plateau.

This work focuses on the hydrology beneath Los Alamos Canyon, as a first step toward developing a predictive tool that can be used to simulate contaminant migration in the canyon. Since water is the carrier fluid for the contaminants of interest, constructing a realistic flow model that captures the most important hydrologic processes of the vadose zone is an essential first step in the development of a reliable model. Although we primarily restrict attention to flow issues, tritium transport in the vadose zone is also modeled here. Tritium, in the form of tritiated water, is an excellent tracer for groundwater, and hence is included in this modeling study as a constraint on the flow model. Although the work here is restricted to Los Alamos Canyon, we anticipate that the methodology and approach applied here can be used to develop models at other sites at the Laboratory.

4-C-2. Hydrostratigraphy

Accurate modeling of groundwater flow and transport in Los Alamos Canyon requires the integration of geologic model information with computational grids. Stratamodel was used to create a three-dimensional geologic framework model for Los Alamos Canyon. The geologic framework model consists of 20 distinct geologic units and is the product of a continuous process of model development and improvement in support of the Hydrogeologic Workplan

(LANL 1998) activities, including the development of numerical flow and transport models such as the present study. The record of model development and improvement is documented in various LANL reports (Vaniman et al. 1996, Carey et al. 1999). The different versions of the geologic models are distinguished based on the fiscal year (FY) in which they were built. Several of the sensitivity analyses were performed with the FY98 version as the geologic basis, while most of simulations are done based on the FY99 version.

The defined stratigraphic units and their accepted designators are listed in Table 4-C-1. Figure 4-C-1 shows a two-dimensional cross section of the geologic model, illustrating the complexity of the current conceptualization of the subsurface. A characteristic of this two-dimensional stratigraphic model that is different than other models developed for sites on the Pajarito Plateau such as MDA G (Birdsell et al. 1999) and Mortandad Canyon (Dander 1998) is the absence of significant thickness of the Tshirege Member of the Bandelier Tuff. Los Alamos Canyon cuts deeply into the Bandelier Tuff such that the Otowi Member is the first unit encountered beneath the alluvium in the canyon bottom over much of the model domain. In the eastern portion of the model, the Otowi is not present, and instead the Cerros del Rio (Tb4) is the first unit encountered. This is the case at R-9, where the stratigraphic section consists only of basalts and the Puye Formation. Figure 4-C-2 depicts the full three-dimensional model stratigraphy, along with the locations of important wells and facilities referred to later.

Table 4-C-2 lists the hydrologic properties used for the Los Alamos Canyon model. Permeability and porosity values used for each unit are listed first, followed by the unsaturated hydrologic parameters for the van Genuchten (1980) formulation used in the present study. It is assumed in this study that hydrologic properties are homogeneous within each individual unit. Although the appropriate hydrologic properties for the various units are thought to be somewhat site dependent, these property values are representative averages of site-wide conditions and can be used as a starting point for vadose zone numerical simulations.

Table 4-C-1.
Stratigraphic Units Present in the Vicinity of Los Alamos Canyon

Group/Formation	Unit Name	Symbol
Tshirege Member of the Bandelier Tuff	Unit 5	Qbt5
	Unit 4	Qbt4
	Unit 3	Qbt3

4-C-3. Infiltration Rates and Water Budget Model

The infiltration rate on the upper surface is one of the most important inputs in simulating flow and transport in the site. For the mesa areas, various hydrologic and chemical techniques have been employed to estimate infiltration rates in various settings. Rogers et al. (1996a) outlined an interpretive technique for estimating local infiltration rates based on measured hydrologic properties and water content values in samples collected from the vadose-zone tuffs. They obtained infiltration rates on mesas as low as 0.06 mm/yr with higher mesa values only found where surface conditions such as ponds were present. In more recent analyses, Birdsell et al. (1999) obtained a value on the order of 1 mm/yr for undisturbed mesa conditions at TA-49, and values estimated from 60-300 mm/yr beneath paved regions. At TA-16, chloride mass balance data collected by Newman (presented in Birdsell et al. 2005) were interpreted using the chloride mass balance method. Infiltration rates slightly higher than 1 mm/yr were obtained in this manner, which is consistent with the analyses of moisture content. Therefore, an infiltration rate of 1 mm/yr is assumed at all locations except the canyon bottom in the current model.

To estimate the infiltration rate along Los Alamos Canyon, we use the study of Gray (1997), who focuses on the water budget and fluid flow in the surface water stream and shallow alluvial aquifer in Los Alamos Canyon. The fundamental model equation used to evaluate the water budget is

$$I = P - R - ET - \Delta S$$

where I is infiltration, P is precipitation, R is runoff, ET is the evapotranspiration term, and ΔS is the change in fluid storage. Since there was no experimental basis for estimating ΔS, Gray assumes it to be zero, listing it as an uncertainty in his analysis. The water budget calculations employed data from several sources, including stream-flow data from three stream-flow gages that provide estimates of surface water flow rates, and meteorological data from five precipitation measurement stations. These data were used by Gray in both an overall water budget for the canyon and a detailed water budget calculation. Details can be found in Gray (1997).

Figure 15 of Gray (1997) shows the results from the overall water budget performed for Los Alamos Canyon. The key result from this aspect of Gray's work is the estimation of the relative amounts of ET, runoff, and infiltration to the deeper vadose zone. Over the three-year period of that study, Gray found that 71% to 83% of the water introduced into Los Alamos Canyon was lost to evapotranspiration. Gray points out many limitations and uncertainties in this estimate. Given the direct influence of this term in the water budget and indirectly on infiltration rate, a more comprehensive study of the processes is warranted. Most of the rest of the water not undergoing evapotranspiration is estimated to be recharging the deeper vadose zone, whereas runoff was found to be relatively small. Average infiltration rates applicable to the Los Alamos Canyon watershed were found to range from roughly 100 to 200 mm/yr for the period of study. These values are average values for the watershed, and might be expected to be higher locally directly beneath the stream channel.

In addition to the overall water budget, Gray (1997) conducted a detailed study using measured data and a numerical model to further break down the components of the water balance. A calibrated numerical flow model of the alluvial aquifer was developed to analyze the spatial and temporal distributions of infiltration in the canyon. Gray divided the canyon alluvial aquifer model into nine zones that corresponded to locations of the monitoring wells used in the model calibration. The model calibration procedure involved adjusting the drain conductance term that controlled the water flux leaving the alluvial aquifer (and entering the underlying bedrock) to match the water level data. The other terms in the water budget (excepting the storage term) were also included in the model, so that the calibration procedure provides a direct estimate of the spatially dependent infiltration rate along the canyon. Table 4-C-3 summarizes the results of this analysis. The highest infiltration rate of 1076 mm/yr occurs in Gray's Zone 4, corresponding to well LAO-0.8. This well falls near the southern projection of the Guaje Mountain fault zone, and was determined to have a strikingly low water level. This observation, and the numerical model calibrated to it, suggest high infiltration in this zone, perhaps due to an enhanced permeability due to fracturing. Zones 1 and 3 also exhibit higher than average infiltration. Gray postulates that Zone 3 may be higher because of its proximity to the Guaje Mountain fault, and Zone 1 infiltration may be high due to a greater saturated thickness in this portion of the canyon. The rest of the Los Alamos Canyon study area exhibited lower infiltration rates.

4-C-4. Contaminant Sources

A host of possible contaminant source sites exist for Los Alamos and DP canyons, resulting from past and present Laboratory operations. The most important of these for our purposes include TA-1 (Townsite), TA-41 (Weapons Development Facility), TA-2 (Omega West Reactor Site), TA-21 (DP Site), and TA-53 (LANSCE). In particular, the Omega West reactor site, located in Los Alamos Canyon, was used since 1943 to house and operate a series of research reactors. Early reactors were fueled by aqueous uranyl solutions, whereas other reactors were fueled by solid fuel elements. A variety of contaminants (mostly radionuclides) are suspected to have been released into the canyon. Most relevant to the present study is tritium, produced from a leak in the primary cooling water system at the reactor. The leak occurred from a break in a weld seam in a section of the delay line running from building TA-2-1 to the surge tank. This leak was discovered in 1993, and tritium was detected within a stretch of canyon corresponding to the southern projection of the Guaje Mountain fault zone. Typical concentrations in the cooling water ranged from 15.7×10^6 to 20.2×10^6 pCi/L. The duration of the leak is not documented, but measurements of tritium concentrations in alluvial aquifer well LAO-1 (located at the eastern boundary of TA-2) suggest that the leak may have begun between November 1969 and January 1970. This reactor was permanently shut down in 1994.

In the transport simulations, among all possible contaminants, we choose tritium, which, in the form of tritiated water, is among the simplest chemical constituents to model because its chemical state as a water molecule implies that it is a tracer for water. Other contaminants may undergo sorption, precipitation, and complex speciation processes that complicate the transport simulation.

Table 4-C-3.
Infiltration Rates for Various Portions of Los Alamos Canyon*

Zone	Location	Infiltration, mm/yr	ET, mm/yr	Downgradient Loss, mm/yr
1	LA Reservoir to 1100 ft east of bridge	714	464	56
2	End of Zone 1 to LAO-C	213	167	223
3	LAO-C to LAO-0.6	566	158	547
4	LAO-0.6 to LAO-0.8	1076	0	148
5	LAO-0.8 to LAO-1	222	195	93
6	LAO-1 to LAO-2	408	28	111
7	LAO-2 to LAO-6	399	93	46
8	State Rt. 4 to Lab boundary	362	139	19
9	East of Lab boundary	325	121	0

* Values from the analysis of Gray (1997)

4-C-5. Numerical Grids

To deal most efficiently with issues of computational demands and model accuracy, we have utilized both two- and three-dimensional models for various flow and transport model analyses. A major advantage of two-dimensional grids is the smaller number of nodes and elements. Calculations run very quickly, making the grid appropriate for scoping calculations and sensitivity studies. When very high spatial resolution is required, three-dimensional grids are also necessary. However, since the grid is two-dimensional, there are limitations as to what spatial variability of flow properties can be captured in the model. In two-dimensional simulations, the model domain implicitly assumes that flow is negligible in the direction normal to the grid. This problem is relaxed in the three-dimensional grid, at the cost of greater computational times and a somewhat reduced grid resolution. Computational grids have been built for both the two-dimensional and three-dimensional simulation models.

For the two-dimensional grid, the western boundary of the domain is located at New Mexico state plane coordinates (492916.5, 541257.7), just west of the Omega Bridge. Note that all state plane coordinates are specified in meters. The eastern boundary extends in a one-dimensional fashion from the western boundary to a coordinate location of (502959.6, 539688), just west of the intersection of State Route (SR) 4 and New Mexico State Highway (NMSH) 502. The extent of Los Alamos Canyon in the two-dimensional model is represented by drawing a one-dimensional line as closely as possible down the center of the canyon. To do this, the length of the canyon was traced from the western to the eastern boundary using a digital topographic map as a reference in Stratamodel (See Figure 4-6). The bends in Los Alamos Canyon are also accounted for. The final version of the two-dimensional grid for Los Alamos canyon consists of 57,004 nodes, 111,256 tetrahedral elements, and contains 11 materials.

In the process of selecting the simulation domain for the three-dimensional Los Alamos Canyon grid, we consider the historical information about contaminant releases and important sites along the canyon that may be relevant to contaminant transport issues in the canyon. It is deemed necessary that areas such as TA-21, TA-2 (the Omega West reactor), DP Canyon, and well R-9 be within the domain of the three-dimensional grid. The Los Alamos Canyon model domain is rectangular in shape and encompasses most of Los Alamos Canyon, DP Canyon, and some of the adjacent mesas to the north and south of Los Alamos Canyon. The model domain extends from the topographic surface to a depth of 1650 meters. Within this grid, we capture both the mesas and the canyon in the same grid, so that infiltration boundary conditions and contaminant releases can be applied correctly. One of the major constraints on the grid building process is to keep the total number of nodes as low as possible but, at the same time ensure that there is adequate resolution in the areas of interest. The final grid, shown in Figures 4-C-3 and 4-C-4, is a three-dimensional grid that is composed of 301,436 nodes, 1,688,457 elements, and 14 unique materials.

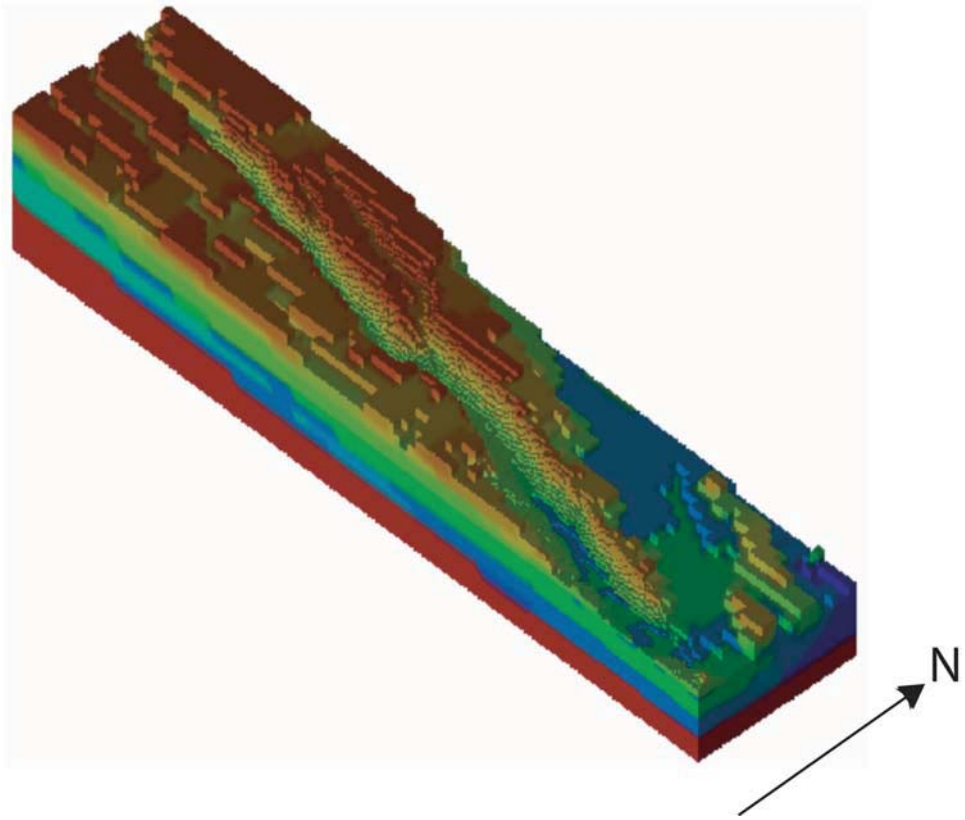

Figure 4-C-4. Three-dimensional view of the Los Alamos Canyon model numerical grid.

4-C-6. Model Implementation

Model implementation issues include how to assign the flow boundary conditions, initial conditions for transient flow, and hydraulic parameters in the model. We will also discuss some assumptions employed in model implementation.

The infiltration values obtained from Gray (1997) in Los Alamos Canyon were applied directly to the two- and three-dimensional models. In the three-dimensional model, it is relatively straightforward to apply an estimated infiltration rate on all grid nodes identified as representing the interface of the alluvium bottom and the bedrock. In a two-dimensional model, we implicitly assume that there are no variations in infiltration in the third dimension (the horizontal direction normal to the canyon). As a result, the appropriate flux to be input to the two-dimensional model is not necessarily the value along the canyon bottom. Figure 4-C-1 shows the infiltration map above the two-dimensional model domain. The infiltration rates so applied in two dimensions are expected to be maximum values. In this study, it is assumed that the relative flux entering the subsurface at different locations along the canyon remains the same, but the absolute value of infiltration is uncertain. The fluid mass flow rate at each top node is determined upon multiplying the infiltration rate at that node by the nodal area normal to the upper surface of the model (for an assumed 1 m thickness of the two-dimensional model domain).

The bottom boundary condition represents the water table. The water table is estimated from results compiled by Keating (personal communication, 1999). Any node falling below this surface is assigned a value of saturation equal to 0.999 to represent the regional aquifer. Therefore, the vadose zone model domain extends only down to this surface, and the bottom region is simply a boundary condition rather than a calculated result.

The hydrologic properties at each grid node in the two- and three-dimensional models are determined by the properties of the unit in which the node falls. The hydrologic properties used for the Los Alamos Canyon model are listed in Table 4-C-2.

It is evident that there is significant uncertainty in the hydrologic properties and infiltration rates due to, for example, the true variability of medium properties, a limited number of measurements, and measurement errors. For the purpose of sensitivity analyses, we defined a base-case set of hydrologic properties and boundary conditions as a reference. In the base case, the values for the hydrologic properties are taken from Table 4-C-2 and the infiltration rate for the canyon is taken from Table 4-C-3 (1 mm/yr for the mesas). The base case parameter set used the mean values of the hydrologic parameters for all units. This practice has been used in other modeling studies on the Plateau, including Dander (1998) and Birdsell et al. (1999). Variations are made on the base-case parameters to examine the impact of uncertain parameters on the model results.

Once the hydrologic properties and initial and boundary conditions are selected, the flow and transport equations are solved using the finite element heat and mass (FEHM) code that simulates heat conduction, heat and mass transfer for multiphase flow within porous and permeable media, and noncondensible gas flow within porous and permeable media. The code handles model geometries in two or three dimensions, and has a variety of solute transport model options available for use. For details of the fundamental model equations solved by the code, see Zyvoloski et al. (1997).

4-C-7. Fluid Saturation Model Results

Figures 4-C-5 and 4-C-6 show a full three-dimensional view of fluid saturation and a series of two-dimensional vertical slices through the three-dimensional model. As expected, the figure shows wet conditions in the canyon, dry in surrounding mesas. As with the two-dimensional model, this model result shows the overriding importance of the stratigraphy in controlling the water contents in the rock. The local infiltration rate also exerts a strong control on the results. Directly beneath the canyon, fluid saturation is much higher within a given stratigraphic unit than in other parts of the model domain, a reflection of the high infiltration in the canyon.

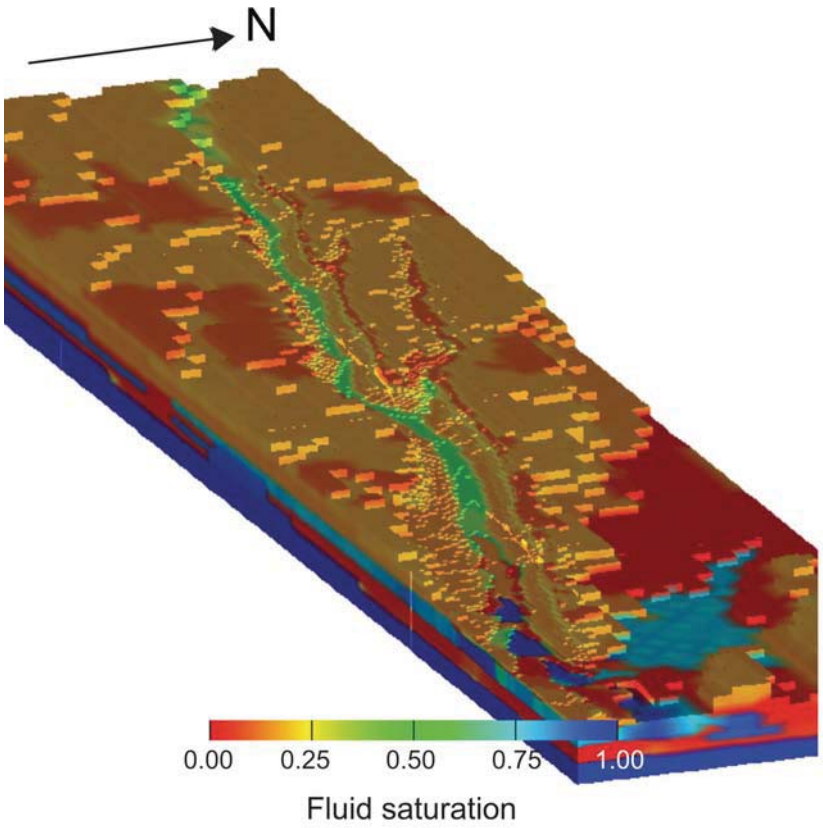

Figure 4-C-5. Full model three-dimensional flow results showing fluid saturation predictions through the model domain.

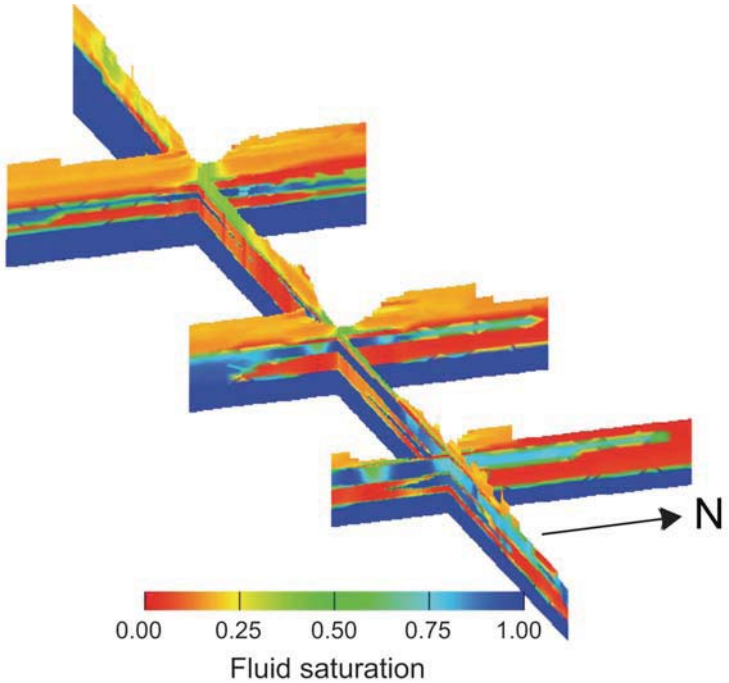

Figure 4-C-6. Fence diagram showing one north-south and three east-west cross-sections.

4-C-7.1 Moisture Comparisons to Data

We choose volumetric water content as the primary measurement used to evaluate the model results because adequate data on water content is available from virtually all vadose zone characterization wells. Robinson et al. (2005a) presents a detailed analysis of the comparisons of volumetric water contents predicted in the three-dimensional model to measured values in three wells located in Los Alamos Canyon: LADP-3, LAOI(A)-1.1, and R-9. Representative results are shown in Figures 4-C-7 and 4-C-8 for wells LADP-3 and LADP-4, respectively. The fits to the data are presented for three different levels of infiltration rates, i.e., the base-case infiltration map, a map with infiltration scaled down by a factor of three from the base map, and a map with infiltration scaled up by a factor of three. It is seen that the base infiltration map does an adequate job of jointly matching the water content profiles in these wells, despite the different stratigraphy and position relative to the canyon bottom. The good fit for LADP-4 illustrates the adequacy of the model in capturing the fluid saturations in the Tshirege Member (not present in the two-dimensional model), as well as in a region where infiltration rates are taken to be significantly lower than in Los Alamos Canyon at LADP-3. The need to apply significantly lower infiltration near LADP-4 is best understood by comparing the water content model and data for these two wells. The significantly wetter conditions in LADP-3 are simulated in the three-dimensional model through the setting of high infiltration in the canyon. It is evident from these comparisons that the model is able to capture the general features of data.

4-C-7.2 Sensitivity Analysis

As was discussed previously, there is significant uncertainty in the hydrologic property values and infiltration rates in the Los Alamos Canyon model. Therefore, it is important to investigate how the deviations of the parameter values from the base case affect the model predictions.

Sensitivity to flow transients. In model simulations presented thus far, it is assumed that the infiltration is time-independent. However, infiltration is likely to be a more transient phenomenon. Gray (1997) shows that in Los Alamos Canyon, water levels in alluvial aquifer wells fluctuate with season in response to summer storm events and spring runoff from snowmelt. It is not clear to what extent these transients are damped by the surface and alluvial aquifer flow processes. To test the potential influence on vadose zone water contents, we take a "worst-case" approach to bound the problem. In the first simulation, we test the sensitivity of the model to a very sharp impulse of water corresponding to the entire predicted infiltration of one-half year concentrated in a one-week time period. This bounding case is intended to model the case of all infiltration occurring in a single spring runoff event and a single summer storm event. Figure 4-C-9a shows the predicted water content profiles in LADP-3 in response to such an event. The influence is only felt in the uppermost ten meters or so of the vadose zone. The quantity of water input during the event, though intense, is insufficient to have a significant influence on the water content profile. These events would then be followed by a half-year of no infiltration, which would cause the profile to bounce back to nearly its original state. Therefore, the assumption of steady-state conditions over time scales of years should have no influence on the interpretation of the water content profiles in the observation wells, except possibly very close to the surface (alluvium-bedrock interface).

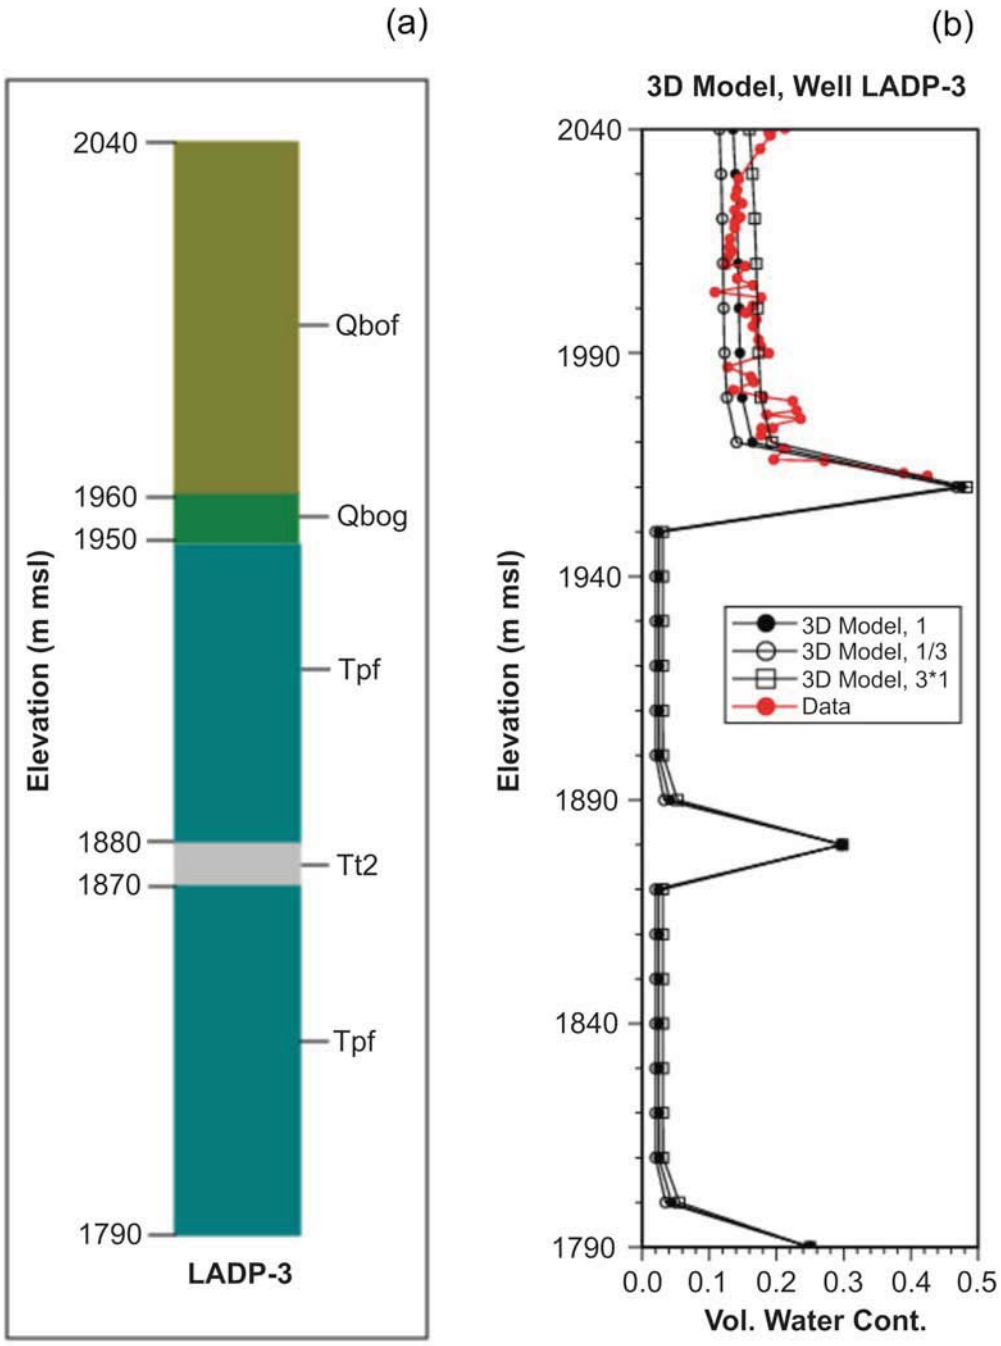

Figure 4-C-7. Comparison of data and three-dimensional model predictions for water contents in well LADP-3 (a. stratigraphy; b. data-model comparison).

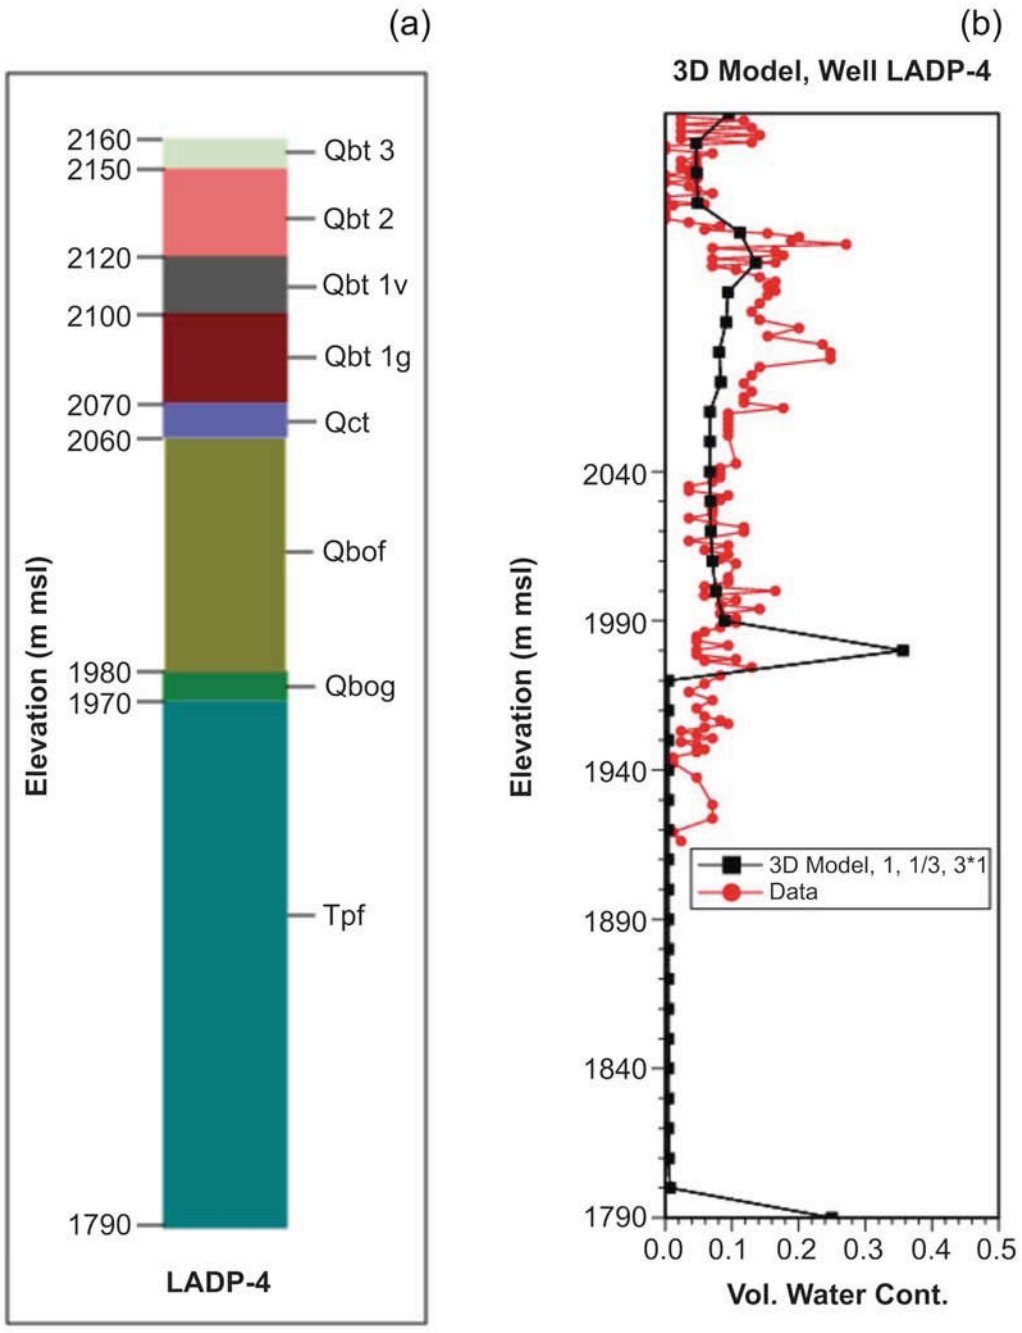

Figure 4-C-8. Comparison of data and three-dimensional model predictions for water contents in well LADP-4 (a. stratigraphy; b. data-model comparison).

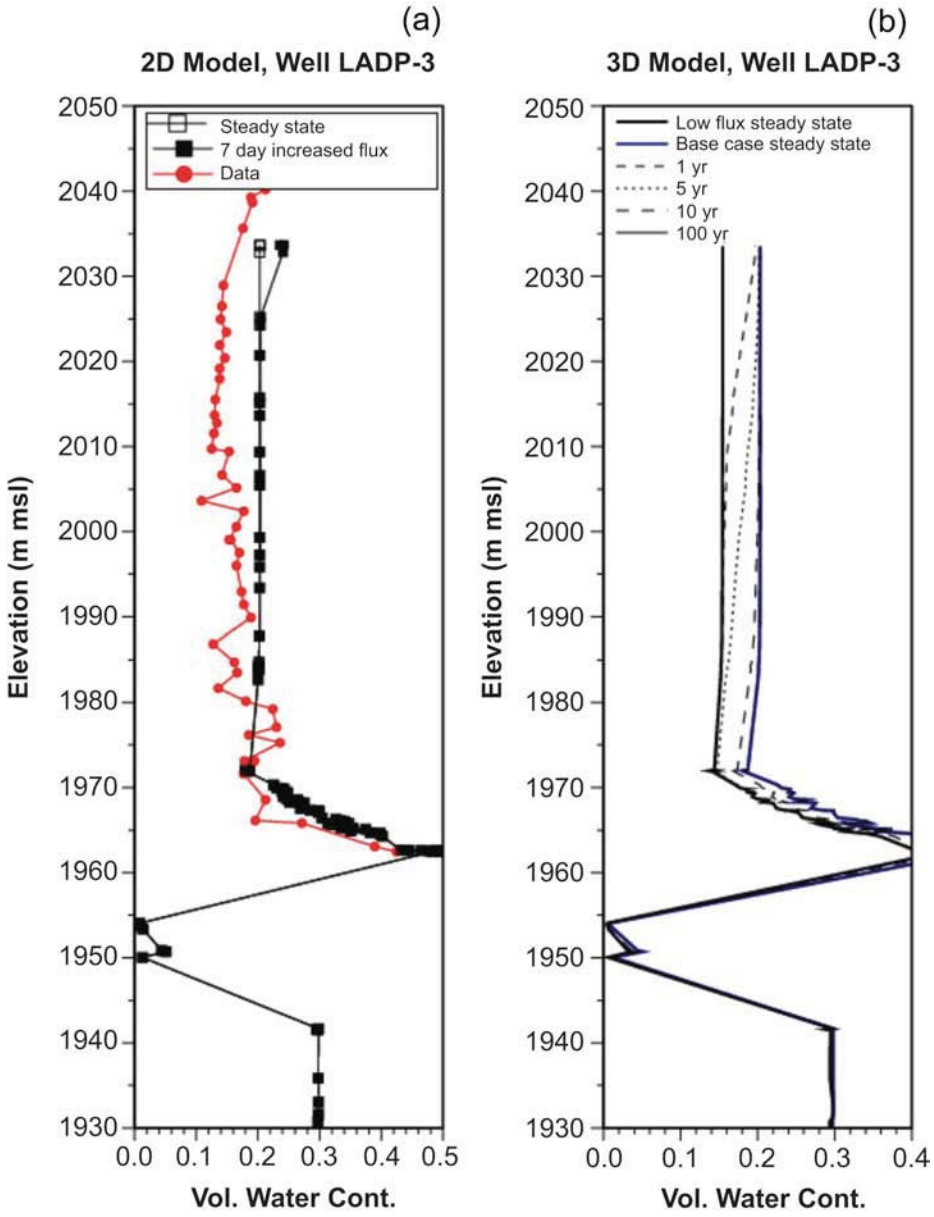

Figure 4-C-9. Two-dimensional model predictions for the water content in response to transient episodes of enhanced infiltration. (a) Well LADP-3, single one-week episode of enhanced infiltration. (b) Well LADP-3, prolonged period of enhanced infiltration (infiltration is increased by a factor of five starting at time 0).

Longer-term variability in the infiltration rate over years or decades could also complicate the interpretation of water content measurements, and thus need to be examined. Figure 4-C-9b shows the results of a simulation in which the infiltration steady state is used as an initial condition, and the rate is increased to the base-case infiltration map at time zero. The plot shows that over a time period of a few years, the water contents increase to significant depths. Within about a decade, the profile throughout the entire section of the Otowi Member reflects the new,

higher infiltration rate. At times of one or a few years, the transient water content profile shows curvature similar to that seen in several of the observation wells, including LADP-3. This does not necessarily mean that the curvature is caused by such a transient, but simply that reasonable variability in infiltration rates over years to decades complicates the interpretation of the water content profiles. This simulation is meant to provide a caution against over-interpretation of the details of the water content profiles. Furthermore, it is recognized from this analysis that the match of a steady-state model to the data in Los Alamos Canyon represents the fluid flow characteristics of the system within the previous ten to 100 years leading up to the collection of the water content data. In general, this result is dependent on the hydrologic conditions of the particular model area. Wet canyon systems with high infiltration rates have transient time periods of this order of magnitude, while dry mesas may take upward of thousands of years to attain a new steady-state water content profile when the infiltration rate changes.

4-C-8. Tritium Modeling Results

Tritium transport model results are presented to further demonstrate the validity of the model and to explore important processes occurring in the vadose zone. Figure 4-C-10 shows the three-dimensional model predictions of the tritium concentration of fluid reaching the water table in the year 1999. Significant, above-background concentrations are predicted along the canyon at locations downstream of where the Bandelier Tuff is not present in the canyon bottom. An important characteristic of the model is the preferential transport to the water table at locations downstream of the confluence of Los Alamos and DP canyons. The main reason for this result is that the thickness of Bandelier Tuff is much greater at upstream locations in the canyon, whereas in the vicinity of R-9, no Bandelier Tuff is present. Recall that the conceptual model for vadose zone flow consists of matrix flow and transport in the Bandelier Tuff, and preferential fracture flow and transport in the basalt units. Rapid transport to the water table at the downstream locations is due to fracture flow in the basalts and fairly rapid transport through the Puye Formation. Therefore, concentration levels in these locations in the canyon are predicted to be significantly greater than zero (in the thousands of pCi/l) in this portion of model domain.

The wells at which tritium concentrations in the regional aquifer can be compared are the water supply well O-4 and test well-3, both located near the confluence of Los Alamos and DP canyons, and characterization wells R-7 and R-9. Well O-4 results indicate that tritium is predicted to be mostly present in the vadose zone; however, a small but non-zero concentration is predicted to have reached the regional aquifer. Well R-7, located downstream of tritium contaminants but upstream of the Los Alamos-DP Canyon confluence, shows the slowest migration rate of tritium. By contrast, the most rapid transport to the water table is observed at R-9, where the peak concentrations of tritium are predicted to already have reached the water table. These model results are consistent with the available field data. Regional aquifer fluid collected in well R-7 has indetectable levels of tritium, whereas TW-3 and R-9 show that tritium has reached the regional aquifer. Determining more quantitatively the ability of the model to reproduce the field data is difficult because of mixing of the tritium percolating from the vadose zone with regional aquifer fluid and the subsequent mixing of contaminated and clean fluid in the wellbore itself. The latter difficulty is especially acute for the water supply wells, which may draw water from hundreds of feet of screened length.

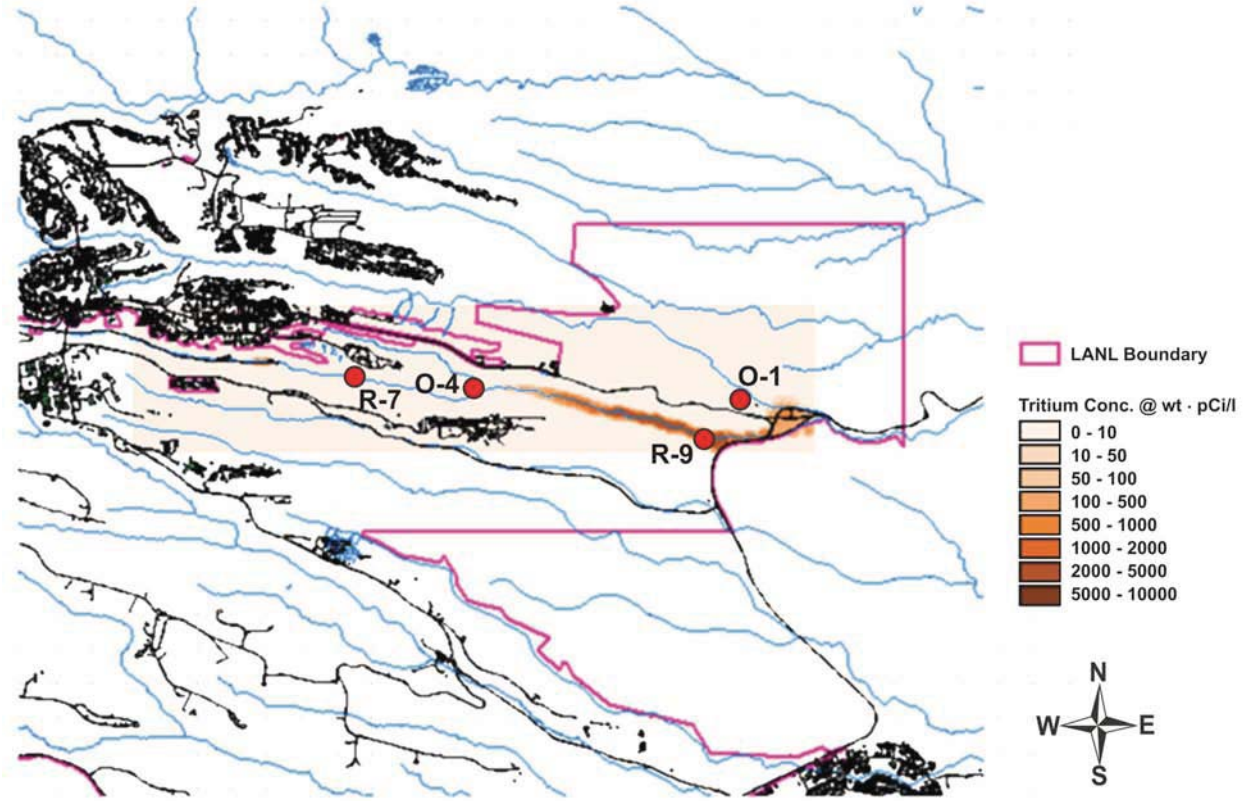

Figure 4-C-10. Three-dimensional model predictions of the tritium concentration of fluid reaching the water table in the year 1999. Significant, above background concentrations are predicted along the canyon at locations downstream of where the Bandelier Tuff is not present in the canyon bottom.

As a final comparison to the available data, we contrast the model results with regional aquifer water supply well O-1. However, because contaminant transport sources from Pueblo Canyon (north of Los Alamos Canyon) were not included in this model, the conclusions related to O-1 are more qualitative. For this comparison, monitoring information (LANL 2001) is used. Contaminants tritium, perchlorate, and nitrate are all thought to be nonsorbing in this system, and thus the combined results of all three contaminants are used in this interpretation. Well O-1 has been found to contain measurable levels of perchlorate at about a 5 ppb level, nitrate levels higher than at other regional aquifer wells in the area, and consistent, above-background levels of tritium in the 30-40 pCi/L range. All observations point to both Laboratory-derived contaminants and effluent discharges from Los Alamos County from past releases in Los Alamos and Pueblo Canyons having traversed the entire vadose zone. The present model explains these observations as a consequence of the hydrostratigraphy along the canyon, with rapid travel times at locations where the Bandelier Tuff is thin or non-existent.

Contrast these results with the transport model for MDA G presented in Appendix 4-B. Most important, travel times through the vadose zone are predicted to be orders of magnitude longer for this mesa site than for transport from the bottom of a wet canyon. The reason for this is straightforward. Infiltration rates, which directly impact transport velocities, are much larger in a canyon setting, in which all water in a catchment is channeled to the canyon bottom. A

significant percentage of that water will escape evapotranspiration and percolate into the deep subsurface along the canyon. In contrast, a mesa top typically provides opportunity for water to drain as surface water, evaporate, or transpire. Therefore, percolation rates are much lower,

APPENDIX 4-D. REGIONAL AQUIFER MODEL DEVELOPMENT

4-D-1. Grid Information

Three-dimensional groundwater models have been developed using FEHM (Zyvoloski et al. 1997); computational grids were generated using LaGriT (Trease et al. 1996). The computational grids for both the basin- and site-scale models are shown in Figures 4-D-1 to 4-D-4; grid characteristics are summarized in Table 4-D-1. The structure of the two models are identical, except for the increased vertical resolution of the site-scale model and the smaller lateral extent.

A view of the upper surface of the basin model grid is shown in Figure 4-D-1. Constant head nodes are indicated by circles. Boundary conditions for the basin-scale model are shown in Figure 4-D-2. A view of the upper surface of the site-scale model is shown in Figure 4-D-3. Boundary conditions for the site-scale model are shown in Figure 4-D-4. Horizontal grid resolution varies from 250 m near the margins to 125 m beneath LANL. Vertical resolution varies from 12.5 m in the upper portion of the aquifer to 500 m at depth.

Each node in the computational mesh is assigned to a unit according to its location relative to the 3-D hydrostratigraphic structure defined by the geologic model. Interpolation from the hydrostratigraphic model to the grid nodes is done by defining closed volumes for each hydrostratigraphic unit. Each node of the mesh can be in one and only one of these volumes. The node properties are assigned based on which volume a node resides in. In this relatively simple approach, the location of contacts between hydrostratigraphic units can only be resolved to the degree of discretization in the finite element mesh. The resulting zonation for the basin and site-scale models are shown in Figures 4-D-5 and 4-D-6.

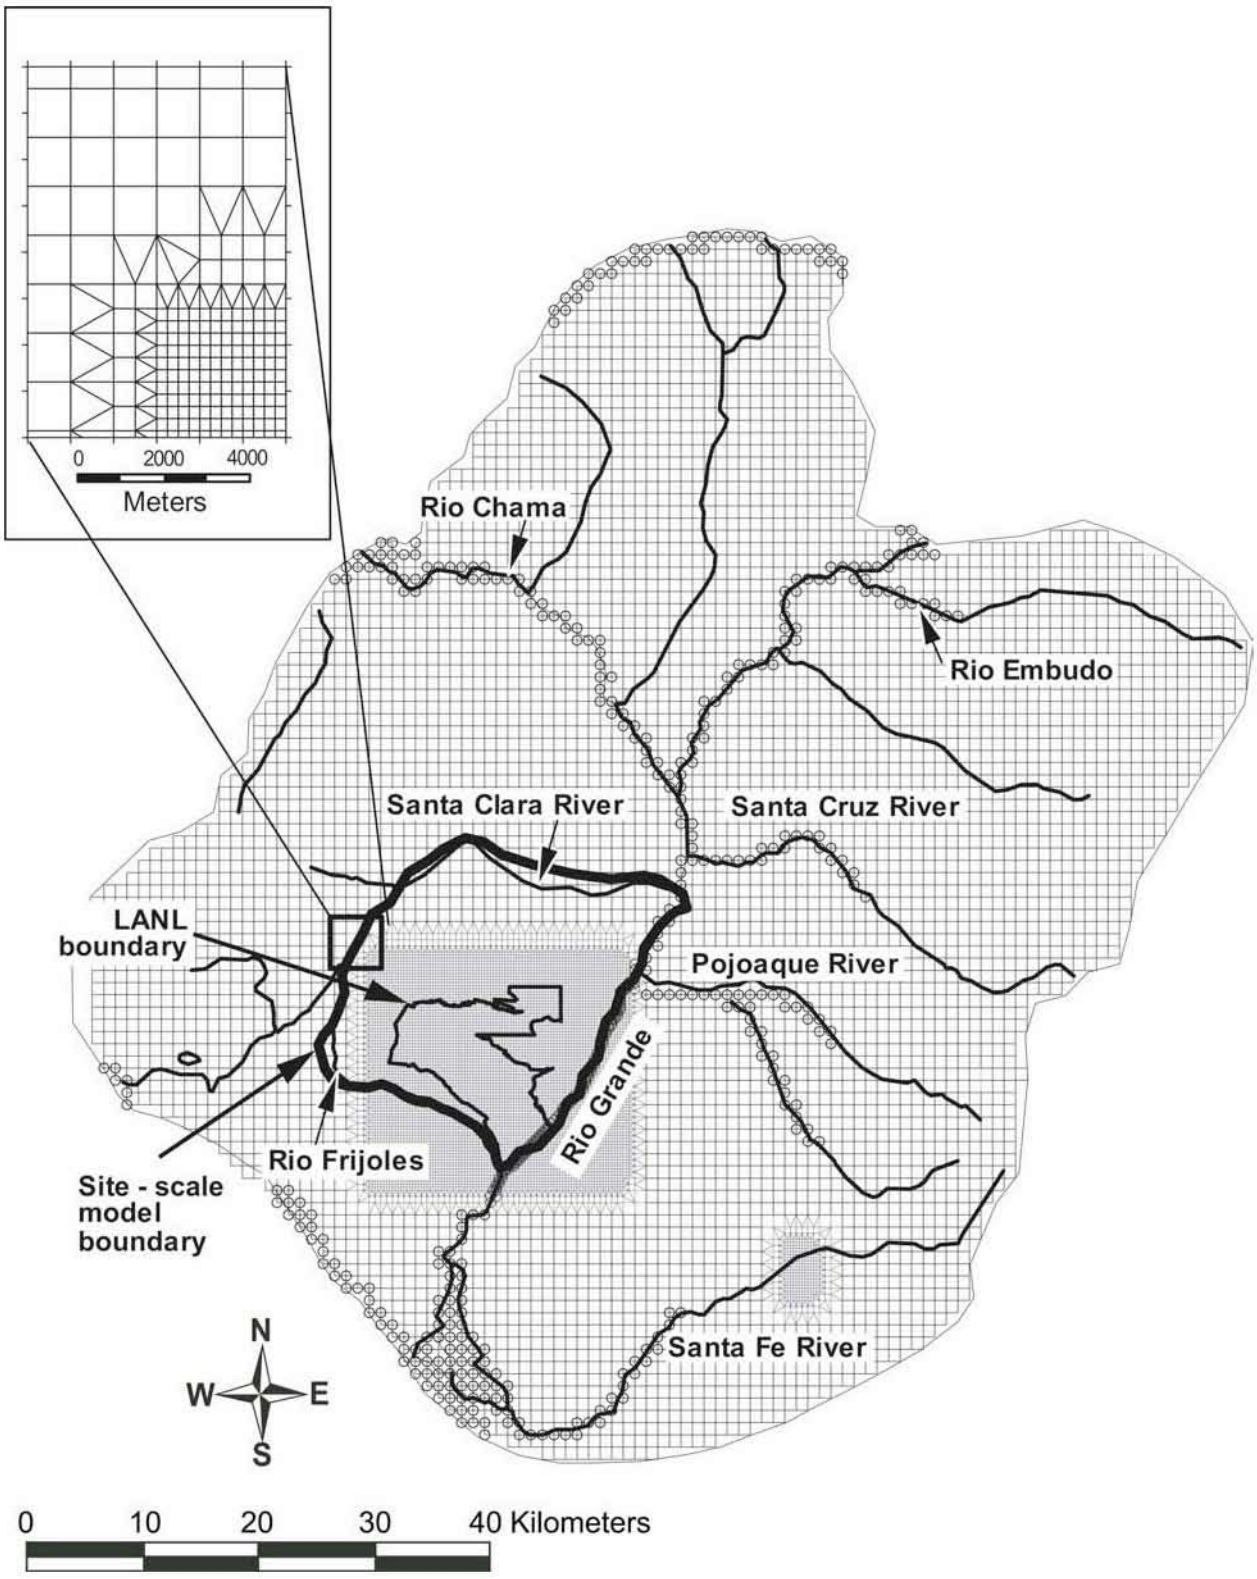

Figure 4-D-1. Top view of basin-scale model grid with side view (inset).

4-D-2. Recharge Model

We define groundwater recharge R over the model domain as follows:

$$R(x,y) = \alpha\, \xi(x,y) \cdot P[Z(x,y)], \tag{1}$$

$$\xi(x,y) = \begin{cases} 1 & Z(x,y) > Z_{\max} \\ \frac{Z_{\max} - Z(x,y)}{Z_{\max} - Z_{\min}} & Z_{\min} < Z(x,y) < Z_{\max} \\ 0 & Z(x,y) < Z_{\min} \end{cases}, \tag{2}$$

where P is precipitation, Z is ground-surface elevation defined from the digital elevation model of the region, ξ is a dimensionless weight function which is characterized by parameters $Z_{\min}$ and $Z_{\max}$, α is the fraction of precipitation that becomes recharge above $Z_{\max}$. Note that $Z_{\min}$ defines the elevation below which no recharge occurs, and above elevation $Z_{\max}$ the recharge is equal to $\alpha\, P$. The total recharge flux Q over the model domain Ω is defined as

$$Q = \iint_{\Omega} R\,dx\,dy = \alpha \iint_{\Omega} \xi P\,dx\,dy = \alpha P'(Z_{\min}, Z_{\max}), \tag{3}$$

where P' is a function of $Z_{\min}$ and $Z_{\max}$ only. We assume $P(Z)$ is a simple linear model with fixed regression parameters, which we derive using annual precipitation data for the region (Bowen, 1992; Spiegel and Baldwin 1963). Thus, there are four unknowns to be estimated (Q, α, $Z_{\min}$ and $Z_{\max}$) coupled through Equation 3. For example, to calculate Q we need to

estimate α, Z_{min} and Z_{max}. For our inverse models, we found it to be more computationally efficient to include Q, Z_{min} and Z_{max} in the estimation process, and compute α as

$$\alpha = \frac{Q}{P'(Z_{min}, Z_{max})}. \quad (4)$$

Precipitation (P) is defined as a function of elevation (Z), according to a regression equation derived from regional data (Spiegel and Baldwin 1963) and Pajarito Plateau data (Rogers 1994). Figure 4-D-7 shows these data; the derived regression relationship is

$$P \text{ (in/yr)} = -16.4 + (.004542) * Z \text{ (feet)}, \; r^2 = 0.9$$

Using a USGS DEM model for the basin, we derive a map of annual precipitation from which the recharge fluxes are derived. We apply focused recharge along the upper reaches of perennial streams in the basin; the ratio of R_f (focused recharge along perennial streams) to Q is an unknown parameter that can be estimated in the inverse analysis. Finally, recharge along ephemeral streams on the Pajarito Plateau is applied in linear proportion to the indices developed by Birdsell (see Nylander 2002). The ratio of this type of recharge to Q is defined as κ.

Figure 4-D-8 shows an example of a recharge model derived using equations 1-4. Note that this particular example applies the highest rates of recharge in the basin to the streams flowing through LANL (>>35 mm/yr). This approach assures that the maximum possible fluxes of contaminants into the regional aquifer are captured in the models. The model parameters employed to generate this particular recharge map are

$$Q = 6400 \text{ kg/s}; \; Z_{min} = 2300 \text{ m}; \; \alpha = 12.5\%; \; \kappa = 0.03, \text{ and } R_f = 0.2.$$

In summary, the full set of recharge model parameters are Q, Z_{min}, Z_{max}, R_f/Q, and κ. These five parameters can be varied to provide a wide range of recharge conditions, all within the calibration constraints of head and baseflow discharge.

[1] Outflow to "west" is outflow to the Albuquerque Basin. For comparison, subsurface inflow to the Albuquerque Basin from the north (including the Española Basin and Jemez Mountains) was estimated to be 19,400 afy (Kernodle et al. 1995), 28,500 afy (McAda and Barroll, 2002), and 2772 afy (Sanford et al. 2004).

APPENDIX 4-E. ESTIMATING AQUIFER DISCHARGE USING STREAMFLOW DATA

The method we use for estimating base flow gain along the Rio Grande is a very simple one, also used by Spiegel and Baldwin (1963), the U.S. Department of Justice (1996), and others. The strategy is to difference measured surface water flow at two gages during January, when other causes of streamflow loss/gain such as evapotranspiration and irrigation withdrawals are likely to be minimal. Because the calculated baseflow gain is generally small compared to total flow in the Rio Grande, small measurement errors in flow at the gages could have large influence on these calculations. The approach applied here assumes that measurement errors are random; therefore, their impact can be minimized by repeating the calculations over a number of years and deriving a long-term mean. Uncertainty in the mean estimate will be an indication of measurement error. Unless the record is much longer than significant temporal trends, temporal trends cannot be ascertained with this method.

We apply this approach to two reaches of the Rio Grande: (1) San Juan Pueblo (828110) to Otowi (8313000) and (2) Otowi (8313000) to Cochiti (8314500). Collectively, these two reaches span the entire length of the Rio Grande that comprises the eastern extent of the Pajarito Plateau, from Santa Clara Creek to Rio Frijoles.

(1) San Juan Pueblo (828110) to Otowi (8313000). A major tributary to the Rio Grande, the Rio Chama, enters this reach just downstream from the gage 8290000 (Rio Chama at Chamita). There was a 23-year period during which all three of these gages were operational (1963 to 1985). By comparing this period of record to a much longer period of record at the Otowi gage (1890–2004), it can be seen that flows were normal during the 1963–1985 period, except two unusually high flow years (1973 and 1975). The January flow at Otowi was highly correlated to, and slightly more than, the sum of flows at San Juan Pueblo and Rio Chama at Chamita, suggesting a consistent base flow gain component along this reach. Three minor tributaries, the Santa Cruz River, the Pojoaque River, and the Santa Clara River, contribute to gain along this reach. Insufficient data during the 1963 to 1985 prevents using measured flows for these years; instead, we use a long-term average from other years, shown in Table 4-E-1.

For each of the 23 year period from 1963 to 1985, we calculated base flow gain during January by the following relationship:

Base flow gain = measured flow (RG Otowi – RG San Juan – Rio Chama, Chamita) – long-term average measured flow (Pojoaque + Santa Clara + Santa Cruz).

The 23-average base flow gain calculated using this approach is 41.2 cfs.(+/- 12.8 at the 95% confidence interval). There is a strong trend evident for gain to be higher in years of higher flow; it is unclear whether this trend is real or is related to sources of error such as small ungaged tributaries which may only be significant at high flow. The adequacy of the derived long-term estimate is shown in Figure 4-E-1a.

(2) Otowi (8313000) to Cochiti (8314500). These two gages have both been operational since 1926, well before pumping began at the Buckman wellfield below Otowi. January flow at the

two stations is highly correlated (r^2=0.96). For most years the data suggest that the reach is gaining; for some years the data suggest a losing reach. One tributary enters the Rio along this reach, Rio Frijoles, which was gaged from 1983 to 1996. We estimate the average January flow at the Rio Frijoles to be 1.2 cfs. Accounting for the inflow from the Rio Frijoles, the gain between these reaches is 13.0 cfs +/- 8.8. The sum of the flow at Otowi and Rio Frijoles and this base flow estimate, compared to the flow at Cochiti, is shown as a yellow line in Figure 4-E-1b.

[1] Their approach includes only those years when the reach was deemed "gaining." ("Losing" years were assumed to be caused by erroneous data and were deleted from the analysis.)

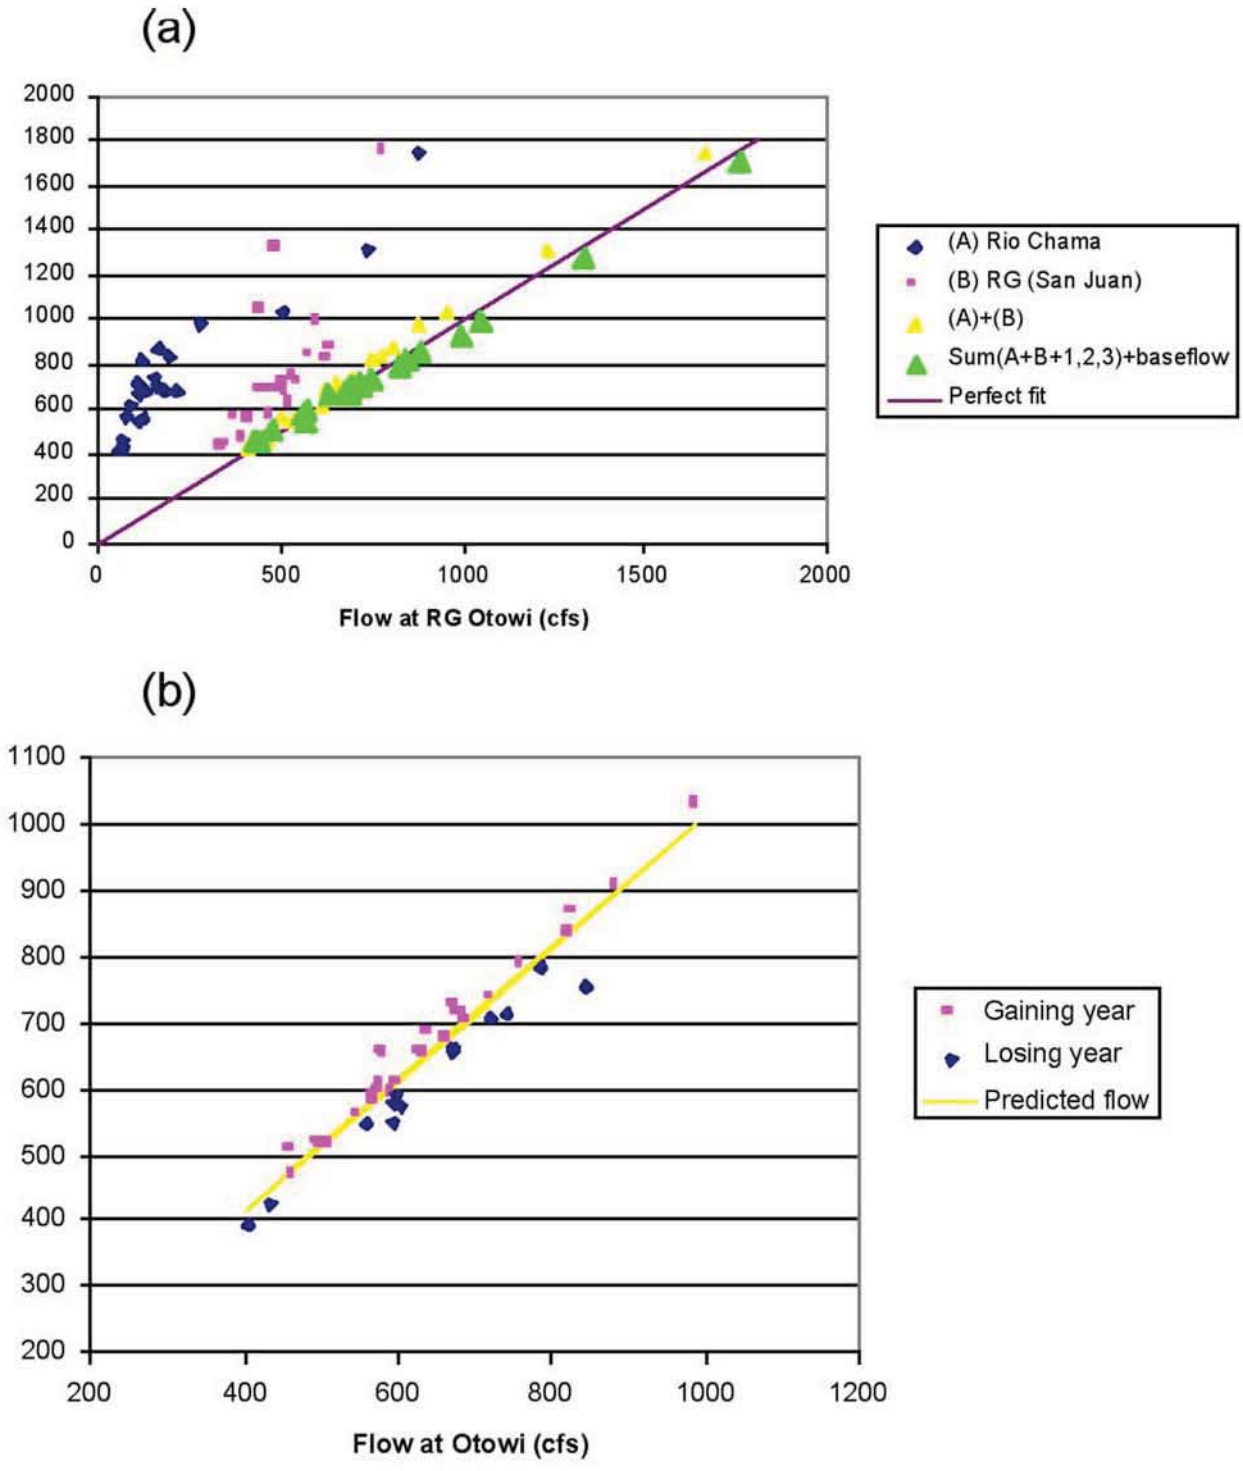

Figure 4-E-1. Measured January flow at the Otowi gage, compared to (a) contributing flow at Rio Chama, Rio Grande at San Juan, minor tributaries, and estimated base flow, and (b) measured January flow at the Cochiti gage.

To extrapolate these estimates to a slightly different reach of the Rio Grande, from Santa Clara Creek to Rio Frijoles, we calculate the ratios of stream lengths within each of the estimated reaches above. Santa Clara to the Otowi Bridge gage is approximately 6/10 the distance of RG San Juan to Otowi Bridge; we estimate 24.7 +/- 7.7 cfs gain along this reach. Otowi to Rio Frijoles is approximately $^1/_2$ the distance of Otowi to the Cochiti gage; for this reach we estimate 6.5 cfs +/- 4.4. In total, our baseflow estimate for the Santa Clara to Rio Frijoles reach of the Rio Grande is 31.2 cfs +/- 12.1 or 884 kg/s +/- 343.

Errors. Sources of errors in the method include systematic errors in streamflow measurements which do not affect all of the streamflow gages used in the differencing equations and which are persistent for the entire period of overlapping record, systematic departures of tributary flows (Pojoaque + Santa Clara + Santa Cruz) from the long-term averages shown in Table 4-E-2 and and unmeasured surface water inflows/outflows. Water budget components are estimated for watersheds in the Española Basin and are shown in Table 4-E-3.

[a] Average basin elevation was calculated by the authors for drainage basins as defined by Wasiolek (1995). No adjustments were made to the average drainage basin elevations to account for the small differences in drainage basin areas between the Anderholm (1994) and Wasiolek (1995) studies.
[b] Precipitation volumes reported by Wasiolek (1995) for winter and spring had already been adjusted to reflect the effects of sublimation of snow. The precipitation volume estimated to exist before before sublimation was determined using information provided by Wasiolek (1995, p. 18). Calculated fractions for evapotranspiration, runoff, recharge, and sublimation reported here for the Wasiolek study are relative to this pre-sublimation precipitation value.
[c] The authors estimated the evapotranspiration (ET) for Anderholm's study based on Anderholm's estimates for precipition (P), runoff (RO), and recharge (R):
$ET = P - RO - R$
[d] These estimates used the chloride-based recharge estimate corrected for runoff from the basin.

Mortandad Canyon Investigation Report

Prepared by the Environmental Programs Directorate

Los Alamos National Laboratory, operated by Los Alamos National Security, LLC, for the U.S. Department of Energy under Contract No. DE-AC52-06NA25396, has prepared this document pursuant to the Compliance Order on Consent, signed March 1, 2005. The Compliance Order on Consent contains requirements for the investigation and cleanup, including corrective action, of contamination at Los Alamos National Laboratory. The U.S. government has rights to use, reproduce, and distribute this document. The public may copy and use this document without charge, provided that this notice and any statement of authorship are reproduced on all copies.

EXECUTIVE SUMMARY

This investigation report for Mortandad Canyon presents the results of studies conducted from 1998 to 2005 in Effluent, Mortandad, and Ten Site Canyons and in an unnamed tributary canyon that heads in Technical Area (TA) 05 of the Los Alamos National Laboratory (the Laboratory). Together these drainage systems comprise the Mortandad watershed. These canyons have received inorganic and organic chemicals and radionuclides since the Laboratory was established in 1943. Most of the contamination related to Laboratory releases is associated with effluent discharges, and discharges of contaminants have decreased over time. The investigations reported herein address sediment, surface water, groundwater, and biota potentially impacted by solid waste management units (SWMUs) and areas of concern (AOCs) located within the watershed. Investigations occurred along 18 km (11 mi) of canyon bottom downcanyon of SWMUs or AOCs. The objectives of the investigations included defining the nature and extent of chemicals of potential concern (COPCs) in sediment, surface water, and groundwater and assessing the potential risks to human health and the environment from these COPCs. The investigations also address the sources, fate, and transport of COPCs in the canyons and evaluate the need for additional characterization or remedial actions.

Sediment investigations included geomorphic mapping, associated geomorphic characterization, and sediment sampling in 27 investigation reaches located downcanyon from SWMUs or AOCs. Analytical data collected in this investigation are supplemented by data collected by the Laboratory's Environmental Surveillance Program and other Laboratory studies to aid in determining spatial and temporal trends in sediment contamination.

Surface water investigations included sampling of persistent water at nine locations in Effluent, Mortandad, and Ten Site Canyons, which are locations where water potentially occurs persistently enough to contribute to human health risks or to adverse ecological effects associated with potential chronic exposure. Surface water and groundwater sampling occurred concurrently in two sampling events to assess relations between these media and to characterize potential seasonal effects on hydrology and contaminant concentrations. Analytical data collected in this investigation are supplemented by Environmental Surveillance Program data to provide a longer period of record and a larger data set.

Groundwater investigations included installing nine alluvial wells, eight perched-intermediate groundwater wells and boreholes, and seven regional groundwater wells within the Mortandad watershed. Data from groundwater samples collected from these wells were supplemented with historical data from preexisting wells. Groundwater investigations also included surface and subsurface geophysical surveys, installation of piezometers, water-level measurements, vector probe and flux meter analyses, and analyses of core samples and vadose-zone pore water.

Sediment COPCs in the Mortandad watershed include 38 inorganic chemicals, 74 organic chemicals, and 17 radionuclides. Surface water and groundwater COPCs include 62 inorganic chemicals, 42 organic chemicals, and 16 radionuclides. These COPCs are derived from a variety of sources, including Laboratory SWMUs and AOCs, runoff from developed areas, and naturally occurring soil, sediment, and bedrock. Assessments in this report focus on the subset of these COPCs considered most important for the evaluation of potential ecological or human health risk. The relative importance of the COPCs was determined by comparing COPC concentrations with human health screening action levels and soil screening levels, ecological screening levels, U.S. Environmental Protection Agency Region 6 and Region 9 tap water values, or U.S. Department of Energy-Derived Concentration Guidelines for drinking water. The sources of the COPCs are also considered in these assessments to determine whether they partially or largely represent Laboratory sources.

The spatial distribution of contaminants in the Mortandad watershed, supported by effluent discharge data, indicates that the TA-50 Radioactive Liquid Waste Treatment Facility (RLWTF) outfall into Effluent Canyon, which has been active since 1963, is the most important source of contamination with respect to potential human health risk and groundwater impacts. Source areas for Laboratory-derived COPCs that are most important in the assessment of potential ecological risk include TA-48 outfalls into the head of Effluent Canyon and into Mortandad Canyon, the TA-50 RLWTF outfall, and additional releases from TA-50 or TA-35 into the head of Ten Site Canyon. The impacts of additional Laboratory sources (e.g., outfalls from the former TA-35 wastewater treatment plant, wastewater lagoons, and filter beds) are indicated by the characterization data, although the concentrations, extent, and inventory of COPCs from these sources are generally minor compared with the sources listed above.

Contaminants in sediment and alluvial groundwater that were originally released from the TA-50 RLWTF outfall are largely or entirely restricted to approximately 4 km (2.5 mi) of canyon bottom downcanyon from the outfall. The infiltration of stormwater into alluvium, particularly upcanyon from the confluence of Mortandad and Ten Site Canyons, results in a complete loss of surface water in most runoff events and deposition of contaminated sediment. The most important sediment deposition area is in the 0.6 km (0.4 mi) of canyon bottom west of the confluence (reach M-3E), and approximately 50% of the inventory of most radionuclides in sediments occurs there. No floods have been recorded crossing the Laboratory-San-Ildefonso Pueblo boundary since RLWTF discharges began in 1963, and only one event before 1963 is recorded as having reached the Laboratory boundary in August 1952.

Contaminant concentrations in sediment, surface water, and alluvial groundwater in the Mortandad watershed have generally decreased over time, indicating that the initial SWMU and AOC sources are no longer major contributors to contamination in canyons media. The canyon bottom sediment deposits contain the largest inventory of adsorbed contaminants that are susceptible to remobilization and transport in floods and are now the primary source for ongoing surface water and alluvial groundwater contamination. Therefore, any future efforts that may be required to address contaminants in canyons media should address the current distribution of contaminants in sediment and associated groundwater rather than the original source areas at Laboratory outfalls.

In contrast, contaminant concentrations in deeper perched-intermediate or regional groundwater have increased over time, indicating the migration of mobile constituents from the alluvial zone into the vadose zone and into deeper zones of saturation. Vadose-zone pore water concentration profiles indicate that these mobile contaminants have percolated in the subsurface. Currently, the majority of the mass of the nonsorbing contaminants nitrate, perchlorate, and tritium is located within the vadose zone, particularly beneath the area near and just east of the confluence of Mortandad and Ten Site Canyons. Chromium is present in the regional aquifer in one characterization well (R-28) above groundwater standards, and chromium, nitrate, perchlorate, and tritium have been measured above groundwater standards in one or more perched-intermediate depth groundwater wells. Iron and manganese have also been measured above drinking water standards in regional groundwater in one well (R-14) and nickel in another well (R-33), although available data indicate that these results represent naturally occurring constituents and not Laboratory-derived contamination.

A baseline ecological risk assessment conducted as part of this investigation evaluates the potential for adverse effects by assessing risks to omnivorous mammals, insect-eating birds, plants, earthworms, aquatic invertebrates, algae, and two threatened and endangered species: the Mexican spotted owl and the southwestern willow flycatcher. Multiple lines of evidence were used to evaluate potential adverse effects on these ecological receptors. Ecological effects data were collected using small-mammal trapping arrays, a cavity-nesting bird monitoring network, seedling germination tests, earthworm mortality tests, and sediment and water toxicity tests. The assessment lines of evidence are augmented by

breeding-bird field surveys, plant surveys, habitat analyses, and spatial modeling of wildlife exposure. The weight of evidence that these investigations provide indicates that no adverse effects to terrestrial and aquatic receptors exist from COPCs in the Mortandad watershed.

The site-specific human health risk assessment uses a trail-user exposure scenario to represent the present-day and reasonably foreseeable future land use in canyons throughout the Mortandad watershed. The assessment results indicate that for the trail-user scenario, no areas in the Mortandad watershed have contaminant concentrations greater than levels acceptable for noncarcinogens (hazard index of 1) or carcinogens (incremental cancer risk criterion of 1×10^{-5}) in sediment or water. However, the radionuclide dose for one area, reach E-1E in Effluent Canyon downcanyon from the TA-50 RLWTF outfall, exceeds the target dose limit of 15 mrem/yr. The calculated dose for reach E-1E, 52 mrem/yr (corresponding to a radiological risk of approximately 2×10^{-4}), is primarily related to external gamma radiation from cesium-137 in sediment. The radionuclide dose limit of 4 mrem/yr in water was not exceeded at any location. Reach E-1E is a short, steep, and rocky area that has no developed trail within the contaminated area, and it is unlikely that recreational users of the Mortandad watershed use this reach as much as is assumed in the trail-user scenario (1 h/d and 200 d/yrr). Other protectively biased assumptions are incorporated into the exposure assessment, also contributing to an overestimate of potential dose. In addition, the area is currently posted as a "soil contamination area," and posting also states that "access is restricted to workers on official business," further discouraging recreational use in reach E-1E. Therefore, no remedial action is proposed to reduce the potential radiation dose to recreational users of Effluent Canyon, although it is recommended that appropriate posting be maintained.

Evaluations of the changes in COPC concentrations over time for sediment, surface water, and alluvial groundwater indicate that concentrations are either relatively stable or are decreasing for contaminants derived from Laboratory SWMUs or AOCs. These decreases are associated with decreased concentrations in TA-50 RLWTF effluent and processes that remobilize, transport, and dilute sediment and waterborne constituents. Radioactive decay also contributes to decreasing concentrations for some radionuclides (e.g., cesium-137, strontium-90, and tritium). Therefore, the potential for impacts to human health or ecosystems from Laboratory-derived contaminants in these media is expected to continue to decrease.

Potential future changes in the vadose-zone contamination and concentrations of contaminants in perched-intermediate and regional groundwater are less well constrained, and a corrective measures evaluation (CME) is necessary to assess the need for remedial actions. The CME will assess the fate of the contaminant mass in the vadose zone and impacts to the regional groundwater where water-supply wells are located. A more detailed evaluation of chromium contamination in groundwater is currently in progress and will be addressed in pending reports to the New Mexico Environment Department. Monitoring in the Mortandad watershed will continue through the proposed CME process and is described in the Interim Facility-Wide Groundwater Monitoring Plan.

In summary, the results of this investigation indicate that human health risks are acceptable for present-day and foreseeable future land uses, assuming that recreational use of Effluent Canyon below the TA-50 RLWTF outfall continues to be discouraged. In addition, no adverse ecological effects were observed within terrestrial and aquatic systems in the Mortandad watershed. Therefore, corrective actions are not needed to mitigate unacceptable risks. However, a CME is proposed to address contamination in groundwater.

1.0 INTRODUCTION

Los Alamos National Laboratory (LANL or the Laboratory) is a multidisciplinary research facility owned by the U.S. Department of Energy (DOE). The Laboratory is located in north-central New Mexico, approximately 90 km (60 mi) northeast of Albuquerque and 30 km (20 mi) northwest of Santa Fe. The Laboratory is currently investigating sites potentially contaminated by past operations to ensure that contaminants do not threaten human health or the environment. The sites under investigation are designated as solid waste management units (SWMUs) or areas of concern (AOCs). Contamination in canyon bottoms and in groundwater is being investigated on a watershed basis between the sources and the Rio Grande, the master drainage in the region, in addition to investigations at individual SWMUs and AOCs.

1.1 Purpose and Scope

This investigation report presents the results of studies conducted from 1998 to 2005 in Mortandad, Effluent, and Ten Site Canyons, and an unnamed tributary to Mortandad Canyon that heads in Technical Area (TA) 05 of the Laboratory. This area is collectively referred to in this report as the Mortandad watershed. The Mortandad watershed above its confluence with the Rio Grande also includes Cañada del Buey and Cedro Canyon, but these canyons are not addressed in this report. Cañada del Buey will be the subject of future investigations under the "Work Plan for Sandia Canyon and Cañada del Buey" (LANL 1999, 64617), and Cedro Canyon is located entirely on San Ildefonso Pueblo land and contains no SWMUs or AOCs. The portion of Mortandad Canyon east of New Mexico State Road (SR) 4 is also not addressed in this report for surface water or sediments because no evidence of contaminant transport past this point has been found (as discussed in Section 7.1.1.6 and in Reneau et al. 2003, 77103). Figure 1.1-1 shows the entire Mortandad watershed and the primary subwatersheds or basins, and Figure 1.1-2 shows more detail within the primary investigation area. The investigations reported herein address sediment, surface water, groundwater, and biota potentially impacted by SWMUs and AOCs located within the Mortandad watershed. These media are collectively referred to as canyons media in this report.

The investigations were conducted to fulfill the requirements of several documents. The "Work Plan for Mortandad Canyon" (hereafter, "the Mortandad Canyon work plan" or "the work plan") (LANL 1997, 56835) describes work scope and regulatory requirements for characterizing the Mortandad watershed for the former Environmental Restoration (ER) Project. It contains a background review of SWMUs and AOCs in the watershed, the history of releases, and a review of contaminant data collected before the work plan was prepared. The New Mexico Environment Department (NMED) approved the work plan in 2002 following the Laboratory's response to a request for supplemental information (RSI) (LANL 1999, 62777; NMED 2002, 73830). The requirement to implement the work plan was also included by reference in Section IV.B.2 ("Mortandad Canyon Watershed") of the Compliance Order on Consent (hereafter, the Consent Order), signed by NMED, DOE, the Regents of the University of California, and the State of New Mexico Attorney General on March 1, 2005.

The investigations conducted for the work plan also followed the technical strategy presented in the "Core Document for Canyons Investigations" (hereafter, "the canyons core document") (LANL 1997, 55622; LANL 1998, 57666). The canyons core document was prepared after a pilot study in Los Alamos and Pueblo Canyons was implemented in 1996, with the goal of standardizing the technical strategy for work in canyons. In 1988, NMED approved the core document following the Laboratory's response to an RSI (LANL 1998, 57666; NMED 1998, 58638).

Two additional documents have been prepared to supplement the work plan. The "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613), approved by NMED in 2004 (NMED 2004,

84463), was prepared to meet requirements in the then-draft Consent Order. This plan replaces the approach and scope of the groundwater and surface water investigations contained in the work plan. The "Mortandad Canyon Biota Investigation Work Plan" (LANL 2005, 89308), approved by NMED in 2005 (NMED 2005, 92084), provides a detailed biota sampling and characterization plan for the Mortandad watershed. This plan satisfies the requirement in the work plan to prepare a biological sampling plan for the Mortandad watershed.

Results of investigations of intermediate and regional groundwater beneath the Mortandad watershed described in the Laboratory's "Hydrogeologic Workplan" (LANL 1998, 59599) are also included in this report. Results of an investigation of chromium contamination in groundwater beneath the Mortandad watershed (LANL 2006, 91987) are not included in this report and will instead be reported in an interim measures report scheduled to be completed in November 2006.

Data collected during the investigations included in this report are used to describe the nature and extent of contamination within the canyon bottom and in groundwater beneath the Mortandad watershed; to update the conceptual model for contaminant distribution and transport within the canyons and underlying groundwater; to assess present-day human health and ecological risk from contaminants within the canyons; to determine and recommend potential remedial actions, if needed, that may be appropriate to achieve or maintain site conditions at an acceptable risk level; and to provide support for decisions at SWMUs and AOCs. The assessments in this report are conducted using data collected since 1998 by the former ER Project to evaluate current environmental conditions. Data from prior investigations and from environmental surveillance sampling are used to help identify temporal trends in contamination and therefore help evaluate how potential risk may change in the future relative to present-day conditions.

This report addresses characterization and risk assessment on the spatial scale of an entire canyon system, encompassing approximately 18 km (11 mi) of canyon bottom downstream of SWMUs and AOCs. The characterization and assessment approach used in this investigation provides an integrating perspective on historical and current contaminant releases to the canyon floor and subsequent contaminant redistribution resulting from various transport processes. This approach facilitates the development of conceptual models that describes expected spatial and temporal trends in contaminant concentrations and inventory, thus supporting recommendations for long-term monitoring. The results also support the Laboratory's watershed approach by providing information on the extent of contamination associated with SWMUs and AOCs and SWMU and AOC aggregates in the watershed and by helping identify and prioritize remedial activities within the watershed. Information on radioactive materials and radionuclides, including the results of sampling and analysis of radioactive constituents, is voluntarily provided to NMED in accordance with DOE policy.

1.2 Organization of Investigation Report

This investigation report has the following sections. The outline follows a format approved by NMED on June 13, 2006 (Goering 2006, 93028). Section 1 is an introduction to the report and to the Mortandad watershed. Section 2 provides background information on the sources and history of contaminant releases, previous investigations of canyons media, and remediation activities that have occurred in the watershed. Section 3 describes the scope of activities in this investigation. Section 4 introduces the field investigations. Section 5 describes the regulatory context of this investigation. Section 6 presents screening-level assessments that identify chemicals of potential concern (COPCs) and that help focus subsequent sections on the subset of the most important COPCs for evaluating potential human health risk. Section 7 presents a physical system conceptual model, including discussions of the nature, sources, extent, fate, and transport of select COPCs that are most relevant for evaluating potential human health and ecological risk and contaminant transport. Section 8 presents baseline ecological and human

health risk results and assessments. Section 9 presents conclusions and recommendations. Section 10 presents references cited in this report.

This report has the following appendixes. Appendix A provides a list of acronyms and abbreviations and a table showing conversion of metric units to U.S. customary units. Appendix B presents field investigation methods and results. Analytical results from this investigation are contained on a compact disk and are included as Appendix C. Appendix D presents supporting information on contaminant trends and inventory. Appendix E presents supporting information on statistics and risk. Appendix F presents an alluvial water-level study. Appendix G discusses subunit variability within alluvium, colluvium, and in the Cerro Toledo interval as it pertains to subsurface hydrology. Appendix H presents results of a resistivity study. Appendix I presents documentation of techniques used in the earthVision model. Appendix J discusses constraints on saturated thickness and lateral extent of perched-intermediate water beneath the Mortandad watershed. Appendix K presents the screening results of stormwater data collected at gage stations in the Mortandad watershed. Appendix L presents an analysis of temporal variability in water-levels observed at the intermediate-depth boreholes in the Mortandad watershed and its relation to surface flow events and barometric pressure changes. Preliminary infiltration investigation results are discussed in Appendix M. Appendix N presents an analysis of spatial variability of the regional water table and generation of a contour map of the water-table elevation. In Appendix O, variability in the regional water table elevation near the Mortandad Canyon is analyzed. Appendix P presents an analysis of variability in the pumping rate and hydraulic heads at the water-supply wells near the Mortandad Canyon.

1.3 Watershed Description

The portion of the Mortandad watershed addressed in this report includes Mortandad Canyon west of SR 4, Effluent Canyon, Ten Site Canyon, and an unnamed tributary canyon that heads in TA-05 (Figure 1.1-2). The watershed heads on the Pajarito Plateau on Laboratory land in TA-03, at an elevation of approximately 2255 m (7400 ft) above sea level (asl), and extends approximately 11 km (7 mi) to SR 4 on San Ildefonso Pueblo land at an elevation of approximately 1965 m (6450 ft) asl, approximately 5 km (3 mi) upcanyon from the Rio Grande. The watershed upcanyon of SR4 has a drainage area of 8.4 km^2 (3.3 mi^2), of which 60% is on Laboratory land and the remaining 40% is on San Ildefonso Pueblo land. Effluent Canyon heads in TA-48 and has a length of approximately 0.8 km (0.5 mi) and a drainage area of 0.3 km^2 (0.1 mi^2), entirely on Laboratory land. Ten Site Canyon heads in TA-50 and has a length of approximately 2.9 km (1.8 mi) and a drainage area of 0.9 km^2 (0.3 mi^2), entirely on Laboratory land. Ten Site Canyon includes a short tributary, referred to as Pratt Canyon, which heads in TA-35. The unnamed tributary canyon that heads in TA-05 has a length of approximately 2.8 km (1.7 mi) and a drainage area of 1.4 km^2 (0.6 mi^2), of which 41% is on Laboratory land and the remaining 59% is on San Ildefonso Pueblo land.

Bedrock geologic units exposed within Mortandad Canyon and tributary canyons upcanyon from SR 4 consist of Quaternary ignimbrites of the Otowi and Tshirege Members of the Bandelier Tuff. Pliocene basaltic rocks of the Cerros del Rio volcanic field and underlying geologic units are exposed farther downcanyon toward the Rio Grande (Griggs 1964, 8795; Smith et al. 1970, 9752; Dethier 1997, 49843; Gardner et al. 1999, 63492; Lavine et al. 2003, 92527). Geologic units within the watershed are discussed in more detail in Section 7 of this report.

A comprehensive overview of the biological setting of the Mortandad watershed is provided in the "Mortandad Canyon Biota Investigation Work Plan" (LANL 2005, 89308). Details on the hydrology are provided in Section 7 and Appendix B of this report.

1.4 Current Land Use

The portion of the Mortandad watershed addressed in this report is located on DOE and San Ildefonso Pueblo lands. Currently, no active Laboratory operations occur in the canyon, except for environmental work such as sediment and water sampling and the discharge of effluent from five National Pollutant Discharge Elimination System (NPDES)-permitted outfalls (Figure 1.1-2 and Plate 1). NPDES outfall 051 discharges treated radioactive effluent from the TA-50 Radioactive Liquid Waste Treatment Facility (RLWTF) into Effluent Canyon. NPDES outfall 03A181 discharges treated cooling water from TA-55 into Effluent Canyon upcanyon from the RLWTF outfall. NPDES outfall 03A021 discharges treated cooling water from TA-03 into the head of Mortandad Canyon. NPDES outfall 03A022 discharges treated cooling water from TA-03 into the upper part of Mortandad Canyon. NPDES outfall 03A160 discharges treated cooling water from TA-50 into the upper part of Ten Site Canyon. There is currently no public access to the watershed on Laboratory land, although trails in the canyons are used by Laboratory personnel for recreational activities such as hiking, running, and bike riding. The portion of the Mortandad watershed on San Ildefonso Pueblo land is undeveloped and is used for traditional activities, including hunting and wood gathering.

2.0 BACKGROUND

Inorganic chemicals, organic chemicals, and radionuclides have been released into the Mortandad watershed from a variety of sources, primarily Laboratory operations in several TAs, since the Laboratory was established in 1943. Most of the contamination related to Laboratory releases is associated with effluent discharges, and releases of contaminants and radionuclides have decreased over time due to improvements in wastewater treatment processes and decreased effluent volumes. The contaminants and radionuclides have been dispersed downcanyon from their release sites in sediments, surface water, and alluvial groundwater. Subsequently, waterborne constituents have percolated into the subsurface and are observed in vadose-zone pore water. Some nonsorbing species are present in intermediate-perched water and in regional groundwater as well. The following sections summarize the sources and history of contaminant and radionuclide releases as well as investigations that address constituent distribution and concentration in canyons media. Remediation activities implemented to reduce contamination in the canyon bottom or in source areas are also discussed.

2.1 Sources and History of Contaminant Releases

This section describes known releases of inorganic chemicals, organic chemicals, and radionuclides that have contributed to contamination within the Mortandad watershed.

2.1.1 TA-50

The Laboratory's RLWTF located at TA-50 began operations in July 1963, and water treatment continues today. The RLWTF discharges treated wastewater to Mortandad Canyon through Effluent Canyon through an outfall that is currently permitted as NPDES outfall 051 [SWMU 50-006(d)] (Plate 1). The largest amount of contamination and radionuclides released to the Mortandad watershed has come from this outfall, which is interchangeably referred to in the remainder of this document at the TA-50 outfall, the RLWTF outfall, or the TA-50 RLWTF outfall. Radioactive liquid waste is treated in Building 50-1 at the RLWTF and transferred to one of two 80,000-L holding tanks located in Building 50-2. When one of the tanks is full, the contents are discharged. Before discharge, the treated wastewater is sampled and tested for radiological and nonradiological constituents. The wastewater is recycled through the treatment plant

until the parameters in the NPDES permit are met. The holding tanks discharge in batches, taking about 30 min per batch. Currently, less than one batch per day is released.

Liquid discharge volumes and associated radionuclide and nitrate releases recorded for the RLWTF from 1963 to 2005 are summarized in Table 2.1-1. This information was collected as part of the historical monitoring of the outfall (LANL 2002, 71301; LANL 2005, 91523; LANL 2006, 93925). Discharge volumes have ranged from the recent low value of 6.8×10^6 L/yr in 2005 to a high of 6.03×10^7 L/yr in 1968, as shown in Figure 2.1-1. Generally, the highest volumes were discharged before about 1981, and volumes have declined since then.

Radionuclides released with the TA-50 RLWTF effluent include americium-241, cesium-137, plutonium 238, plutonium-239,240, strontium-89,90, and tritium. From 1963 to 2004, discharge records indicate that a minimum total of approximately 0.156 Ci of americium-241, more than 2 Ci of cesium-137, more than 0.10 Ci of plutonium-238, nearly 0.2 Ci of plutonium-239,240, approximately 1.5 Ci of strontium-89,90, and approximately 823 Ci of tritium were discharged. Most of the radionuclides americium-241, cesium-137, plutonium-238, and plutonium-239,240 apparently were discharged between 1972 and 1983, although records are incomplete before 1973 (Table 2.1-1). Much of the cesium-137, strontium-90, and tritium have been lost since initial discharge by radioactive decay, although essentially all of the other radionuclides with longer half-lives remain in the watershed.

The variability in discharge volume and in contaminant releases over time (Table 2.1-1) reflects contemporaneous Laboratory operations whose wastewater was treated at the RLWTF, new wastewater treatment methods, and evolving regulatory requirements. Historic nitrate concentrations are compared with outfall volumes in Figure 2.1-1. These illustrate that time histories of released contaminant concentrations do not necessarily track those of outfall volumes. Advanced treatment technologies and stricter regulatory requirements have resulted in reduced contaminant concentrations in effluent. For example, a new reverse osmosis and ultrafiltration system began operating at the RLWTF in 1999 to remove additional radionuclides (except tritium) from the effluent and to ensure that the discharges meet DOE public dose guidelines. Also in 1999, the RLWTF instituted a program to restrict the discharge of nitrogenous wastes into the facility's collection system. The combination of these restrictions with the ultrafiltration system has decreased the nitrate (nitrate as nitrogen) effluent concentration to below 10 mg/L. Since 2000, tritium releases have also decreased because of segregation and evaporation of tritium-contaminated waste streams. The effects of these facility enhancements can be seen in the recent information given in Table 2.1-1.

Measurement of perchlorate releases in RLWTF liquid effluent began in 2000. That year, the RLWTF discharged 4.74 kg of perchlorate for an average concentration of 254 μg/L in the effluent. In 2001, 2.29 kg of perchlorate was released, resulting in an average concentration of 169 μg/L. In 2002, ion-exchange resins were installed at the RLWTF, and this addition has successfully reduced perchlorate in effluent to below the detection limit of 4 μg/L. Other inorganic chemicals released with RLWTF wastewater include chromium, fluoride, sodium, and chloride. Historic chromium releases since 1976 are shown in Figure 2.1-2; the estimated mass of chromium released since 1976 is 26 kg.

Fluoride is also released at the TA-50 RLWTF outfall. Highest effluent concentrations occurred between 1982 and 1990, ranging from about 6 mg/L to a maximum of 28 mg/L. Since 1999, enhanced fluoride treatment has kept effluent concentrations below the New Mexico groundwater standard of 1.6 mg/L. In 2005, the average effluent fluoride concentration was 0.24 mg/L (LANL 2006, 93925).

Before 1975, outfalls at TA-50 (other than the RLWTF) discharged into the head of Ten Site Canyon through drain lines originating in Buildings TA-50-1 and TA-50-2 (LANL 1997, 56835, pp. 2-22–2-23). In 1974, two unplanned releases of untreated waste occurred because of overflow of a sump in TA-50-2.

The drain lines were removed in 1982, and cesium-137, plutonium-239, ruthenium-106, strontium-89, strontium-90, and yitrium-90 were encountered during excavation of the lines. The area near the head of Ten Site Canyon was partially decontaminated in 1981. A Resource Conservation and Recovery Act (RCRA) field investigation (RCRA RFI) was performed in 1993 for SWMU 50-006(a). Soil samples were collected near the outfalls of the two former drain lines, on both banks of the drainage channel, and in the canyon drainage channel at a distance of about 1300 ft downstream from the TA-50 boundary. COPCs identified included polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and the radionuclides americium-241, cobalt-60, cesium-137, potassium-40, plutonium-238, plutonium-239,240, Ra-226, strontium-90, and thorium-232 (LANL 1997, 56835, pp. 2-22, 2-23).

2.1.2 TA-35

Historic outfalls located at TA-35 (Figure 1.1-2 and Plate 1), formerly called Ten Site, are sources of radionuclides and other contamination in the watershed. TA-35 is highly developed industrially, and stormwater runoff from paved areas may also contribute to contaminants in the watershed. The following paragraphs summarize source information compiled in the Mortandad Canyon Work Plan (LANL 1997, 56835).

From 1951 to 1963, treated wastewater containing radionuclides was discharged from the Ten Site Laboratory (Building TA-35-2) into Pratt Canyon (SWMU 35-003(d)-00), a small tributary of Ten Site Canyon. This wastewater originated while hot cells were used to prepare kilocurie sources of radioactive lanthanum (lanthanum-140) and barium (barium-140), waste from experimental reactors (Los Alamos power reactor experiment-1 and -2 and Los Alamos molten plutonium reactor experiment), plutonium research laboratories, and a tritium laboratory. During the operation of the TA-35 wastewater treatment plant (WWTP), approximately 2.7 × 106 gal. (10,220 m^3) of water were discharged to Pratt Canyon (LANL 1997, 56835). The total activity discharged was about 20 Ci gross-beta activity and 1.4 Ci of strontium-89 and strontium-90. The gross-beta activity consisted of a combination of barium-140, lanthanum-140, strontium-89, strontium-90, and trace amounts of cesium-137, ruthinium-106, plutonium, technetium-99, and uranium (Emelity 1958, 793; LANL 1997, 5683; Aeby 1952, 741; Aeby 1954, 742). Many of these radionuclides are short lived, and a decay-corrected inventory estimate made in 1996 considering barium-140, lanthanum-140, strontium-89, and strontium-90 calculated that approximately only 0.2 Ci of strontium-90 remained from the historic releases at TA-35 (LANL 1997, 56835). Unknown quantities of tritium were also disposed of from 1953 to 1974 (Rogers 1998, 59169, p. 2). In addition, chemicals such as nitric acid, strontium nitrate, iron sulfate, and ferric chlorate were released to Pratt Canyon either as wastewater constituents or as treatment chemicals. The TA-35 WWTP was closed in 1963, underwent initial decontamination and decommissioning (D&D) in 1984 and 1985 (Elder et al. 1986, 03089), and underwent further D&D in 1995 and 1996 (LANL 1997, 56835).

Sanitary septic systems that previously discharged from TA-35 were also a source of nitrates in the Mortandad watershed. From 1951 to 1975, two septic systems discharged to Mortandad Canyon and two discharged to Ten Site Canyon. These four systems had no documented releases of contaminants other than treated sewage (LANL 1997, 56835). From 1975 to 1992, the TA-35 sanitary septic sewage lagoons released treated effluent to Ten Site Canyon at NPDES-permitted outfall 10S. Records from 1987 to 1992 show that an average of 45,000 gal. was discharged daily (LANL 1997, 56835).

Photographic waste discharge, noncontact cooling water, and treated cooling water were also previously released at now inactive outfalls into Ten Site and Mortandad Canyons. Chromium may have been released with some cooling water, especially from NPDES-permitted outfall 04A-127.

Currently, only NPDES-permitted outfall 03A160 (Plate 1) discharges from TA-35. It discharges cooling tower blowdown associated with a large generator within Building TA-35-124 to Ten Site Canyon above reach TS-1W.

2.1.3 TA-48

Radiochemistry and nuclear medicine research has been conducted at TA-48 (Figure 1.1-2 and Plate 1), the Radiochemistry Site, since 1957. Discharges to Mortandad Canyon and to the head of Effluent Canyon from TA-48 are believed to have begun at about that time (LANL 1997, 56835). Historically, outfalls handling once-through cooling water and treated cooling tower blowdown have discharged to the canyons [SWMUs 48-007(a), 48-007(b), 48-007(d), 48-010)]; additional small wastewater sources such as floor, roof, and sink drains [SWMUs 48-007(c) and 48-007(f)] also existed. Soil samples collected at these sites in 1993, 1995, and/or 1997 showed the presence of radionuclides and inorganic chemicals. Some radionuclides observed were americium-241, cobalt-60, cesium-137, sodium-22, plutonium isotopes, ruthinium-106, and strontium-90 and uranium isotopes; some inorganic chemicals detected above background levels were barium, copper, lead, mercury, manganese, strontium, and zinc. Currently, no NPDES-permitted outfalls are present at TA-48.

In addition to liquid effluent, the air exhaust system at TA-48 vented acidic vapors (such as perchloric, hydrochloric, hydrofluoric, and nitric acids) that may have contributed contaminants to that watershed.

2.1.4 TA-03

A small portion of the southern part of TA-03, mainly near the Chemistry and Metallurgy Research (CMR) Building (Building TA-03-29) and the Materials Science Laboratory (Building TA-03-1698), is located in the upper reaches of the Mortandad watershed. Some unintentional spills to Mortandad Canyon have occurred, as summarized in the Mortandad Canyon Work Plan (LANL 1997, 56835).

- Six releases of cooling water from the new Sigma Building occurred before 1975; no information was reported regarding possible contaminants associated with the cooling water (Purtymun 1964, 11822).
- During summer 1974, two accidental releases from a radioactive liquid-waste line (near the CMR building) resulted in radioactive contamination of soil near the leaks, SWMU 03-054(e). The waste contained predominantly plutonium-238, with lesser concentrations of cesium-137, plutonium-239, strontium-89, and strontium-90. Remediation of soils was conducted in 1974 and 1984.

Treated cooling water and electroplating solutions were released at SWMU 03-049(a) starting in 1960. Trace amounts of metals (including chromium), acids, cyanide, and depleted uranium were likely released with electroplating rinse waters.

Currently, NPDES-permitted outfalls 03A021 (CMR Building seasonal cooling) and 03A022 (Sigma Complex seasonal cooling) discharge treated cooling water to the upper part of Mortandad Canyon at TA-03 (Plate 1).

In addition to the TA-03 sites located around Mortandad Canyon, it is possible that potassium chromate discharged from TA-03 into Sandia Canyon may be a source of chromium contamination observed in the regional aquifer at well R-28 in Mortandad Canyon (LANL 2006, 91987). Potassium chromate was used from approximately 1956 to 1972 as a corrosion inhibitor in the cooling towers that serviced the TA-03 Power Plant. Possible usage averaging 16.3 kg/d (35.9 lb/d) (DOE 1987, 52975) makes this the largest

known usage of chromium at the Laboratory. Cooling tower blowdown was discharged through an outfall to Sandia Canyon (currently NPDES-permitted outfall 01A001) at approximate rates of 128,000 to 288,000 gal./d. Chromium contamination is being further investigated under the "Interim Measures Work Plan for Chromium Contamination in Groundwater" (LANL 2006, 91987).

2.1.5 TA-55

TA-55 was established in 1973 for the plutonium-processing laboratory. Activities include chemical and metallurgical processes for recovering, purifying, and converting plutonium and other actinides into many compounds and forms. Waste streams are treated at the TA-50 RLWTF. NPDES-permitted outfall 03A181 (Plate 1) currently discharges to upper Effluent Canyon near reach E-1W and west of outfall 051. This outfall releases small volumes of treated blowdown from a cooling tower.

2.1.6 Other Technical Areas

SWMUs and AOCs at several other Laboratory TAs within the Mortandad watershed could have potentially contributed contamination to the canyon bottoms, including TA-60, former TA-04, TA-05, TA-52, former TA-42, and TA-63. Firing sites and outfalls at TA-05 that were active from approximately 1944 to 1959 are the only sources of potential contamination for an unnamed tributary canyon that joins Mortandad Canyon immediately east of the Laboratory-San Ildefonso Pueblo boundary (LANL 1997, 56835, p. 2-11).

2.1.7 Runoff from Developed Areas

The Laboratory's technical areas that surround Mortandad Canyon are industrially developed, including Laboratory facilities, storage locations, and parking lots. Runoff from developed areas transport various contaminants associated with urban areas into the canyons. Contaminants commonly found below developed areas include constituents in motor oil, gasoline, diesel, and asphalt, road salt, PCBs, heavy metals, and pesticides. PAHs, suspected carcinogens that are frequently associated with vehicle usage and asphalt, are a common class of contaminants associated with developed areas (Edwards 1983, 82302; Lopes and Dionne 1998, 82309; van Metre et al. 2000, 82262). Metals that have been identified as associated with runoff from roads include cadmium, chromium, copper, lead, nickel, and zinc (Walker et al. 1999, 82308; Breault and Granato 2000, 82310). Consistent with studies in other regions, investigations in other canyons in and near the Laboratory have identified various inorganic and organic COPCs as being associated with runoff from developed areas (LANL 2004, 87390, pp. 7-14, 7-16).

2.1.8 Cerro Grande Fire

In May 2000, the Cerro Grande fire burned a large part of the Mortandad watershed west of SR 4. Approximately 5.7 km^2 (1410 acres) of the watershed was within the burn perimeter (BAER 2000, 72659), comprising 68% of the watershed above the highway. Most of this area, 82%, was classified as low burn severity or not burned and the remainder as moderate burn severity. Various naturally occurring inorganic chemicals (e.g., barium, cobalt, and manganese) and anthropogenically created fallout radionuclides (e.g., cesium-137, plutonium-239,240, and strontium-90) were concentrated in Cerro Grande ash at levels exceeding that of background sediments before the fire, and the transport of ash has resulted in elevated levels of these analytes in post-fire sediment deposits in some canyons (Katzman et al. 2001, 72660; Kraig et al. 2002, 85536; LANL 2004, 87390). Elevated levels of inorganic chemicals and radionuclides that can be attributed to the transport of ash have also been found in stormwater samples in some canyons (Gallaher and Koch 2004, 88747). Post-fire changes in sediment or water chemistry may have

occurred in the Mortandad watershed, although these effects are expected to be relatively minor compared with other canyons because of the low burn severity and because no layers of ash-rich sediment have been observed.

2.2 Contamination in Canyons Media

Contamination in sediment, surface water, and groundwater in the Mortandad watershed has been evaluated in many studies before this report, dating back to 1956 (Purtymun et al. 1965, 11847). This previous work documented the presence of elevated levels of inorganic chemicals, organic chemicals, and radionuclides in canyon media and has evaluated the potential effects of contaminants on biota. Some key studies, summarized below, provide background and supplemental data for the investigations presented in this report. Relevant information from these studies is also included in subsequent sections of this report.

2.2.1 U.S. Geological Survey

The U.S. Geological Survey (USGS) performed initial studies of contaminants in the Mortandad watershed, beginning with sampling and analyzing sediment below the TA-35 WWTP outfall into Pratt Canyon in 1956 (Purtymun et al. 1965, 11847) and continuing with studies in Effluent and Mortandad Canyons (Purtymun et al. 1966, 11848; Purtymun 1967, 8987; Purtymun and Kunkler 1967, 8888). This work provides documentation of contamination in the initial years of effluent discharge in the watershed and of downcanyon decreases in radionuclide concentration at that time.

2.2.2 Environmental Surveillance Program

The Laboratory's Environmental Surveillance Program (ESP) has sampled and analyzed sediments, surface water, and groundwater at numerous locations in the Mortandad watershed since 1969. This work, reported in annual Environmental Surveillance reports (e.g., ESP 2001, 71301; ESP 2002, 73876; ESP 2004, 83635; ESP 2004, 88421; ESP 2005, 92222) and in other reports (e.g., Purtymun 1971, 4795; Purtymun 1973, 4971; Purtymun 1974, 5476; Purtymun 1975, 11787; Purtymun et al. 1977, 11846; Purtymun et al. 1983, 6407; Devaurs and Purtymun 1985, 7415; Stoker et al. 1991, 7530; Ferenbaugh and Gladney 1997, 93715; Gallaher et al. 1997, 59165), supports the evaluation of long-term trends in contamination in different media and an understanding of the role of stormwater transport.

2.2.3 Environmental Science Group

The Laboratory's Environmental Science Group conducted a series of detailed studies of radionuclides in sediments within the Mortandad watershed in the 1970s; this group has also conducted ecological investigations in contaminated canyon-bottom areas (Hakonson et al. 1973, 4974; Hakonson and Bostick 1976, 29678; Hakonson et al. 1976, 8920; Nyhan et al. 1976, 11746; Nyhan et al. 1976, 11747; Nyhan et al. 1978, 5726; Hakonson et al. 1980, 8924; Nyhan et al. 1982, 7164). This work included documenting downstream changes in contaminant concentrations and relations between contaminant concentration and sediment particle size in the canyon below the RLWTF outfall into Effluent Canyon.

2.2.4 Ecology Group

The Laboratory's Ecology Group has conducted studies on the uptake of contaminants by biota in Mortandad Canyon. These studies include addressing potential uptake of contaminants by small mammals and plants (Bennett et al. 1996, 56035), peregrine falcons (Podolsky 2000, 73477), and an

initial ecotoxicological risk screen in Effluent and Mortandad Canyons (Gonzales and Newall 1996, 56045). Additional studies by the Ecology Group were conducted as part of this investigation and are summarized in Section 8.1.

2.2.5 Environmental Restoration Project

Since 1998, detailed studies of canyons media in the Mortandad watershed have been conducted by the former ER Project and successor organizations. Summaries of results of sediment investigations through 2003 have been presented previously (Reneau et al. 2003, 77103; LANL 2005, 89308). Supplemental data on contamination in canyons media are available through other ER Project reports (e.g., LANL 1995, 49925; LANL 1996, 54422; LANL 2005, 91699). The work presented in this investigation report builds on these previous studies.

2.2.6 NMED and EPA

NMED and the U.S. Environmental Protection Agency (EPA) and their subcontractors have collected and analyzed samples from canyons media in the Mortandad watershed as part of oversight activities (e.g., Hanlon-Mayer and Jacquez 2000, 82261; EPA 2001, 70669). These data provide supplemental information about contamination in the watershed.

2.3 Remediation Activities

Several remediation activities in the Mortandad watershed have reduced the potential for contaminant transport or reduced the concentrations or inventory of contaminants in canyon media. The activities most relevant to this investigation are summarized below.

2.3.1 Pratt Canyon

After removing structures at the former TA-35 WWTP at the head of Pratt Canyon in the early to mid-1980s [SWMUs 35-003(d,e,l,q)], backfill was placed at the head of the canyon to fill excavations and prevent erosion of potentially contaminated soil. Subsequent runoff events incised the backfill on the slope, leading to concerns about remobilizing contaminants such as strontium-90. In 1996, the ER Project conducted an interim action (IA) in Pratt Canyon to reduce the potential for erosion (LANL 1996, 55809). The IA activities included replacing fill in the incised channel, stabilizing the slope, and installing a berm to divert runoff from the slope.

2.3.2 Ten Site Canyon

Excavation of contaminated sediment from Ten Site Canyon reach TS-1W (Plates 1 and 3) occurred in an IA in 1996 (LANL 1997, 55834). This IA targeted a location in the stream channel where unusually high concentrations of plutonium-238 (5190 pCi/g) had been found in one sample, which is the maximum reported anywhere in the Mortandad watershed. This contamination was derived from accidental releases from TA-50 in 1974, designated SWMU/AOC 50-006(a). The site has been described as a “hummock,” and the geomorphic setting indicates that the location was probably a sandbar next to a scour hole that formed below boulders in the channel. Only a single sample from this area had plutonium concentrations >100 pCi/g, suggesting that the 5190 pCi/g result was anomalous and included a small particle of plutonium. A total of 0.55 m^3 (0.72 yd^3) of sediment was removed in this IA.

2.3.3 Sediment Traps

Sediment deposits were excavated from sediment traps #1 and #3 in Mortandad Canyon reach M-4 (Plates 1 and 4) in June 2000 after the Cerro Grande fire (WGII 2000, 70735). This sediment removal was intended to increase capacity in trap #1 to prepare for possible post-fire floods and to remove some fine-grained sediment in trap #3. Excavation of a fill pile adjacent to trap #1 that resulted from prior trap maintenance activities in 1992 also occurred. An estimated 1680 m^3 (2200 yd^3) of sediment was removed in these activities. The contaminant inventory removed in these activities is probably relatively low, compared with the total inventory in reach M-4 because measured radionuclide concentrations in the traps and the fill piles were relatively low. In addition, much of the excavated volume probably consisted of sediment that predated contaminant releases in the watershed.

2.3.4 Permeable Reactive Barrier

In January and February 2003, the Laboratory installed a permeable reactive barrier (PRB) in Mortandad Canyon reach M-3W to evaluate in situ treatment of a suite of COPCs in shallow alluvial groundwater (Kaszuba et al. 2002, 93891; DBS&A 2006, 93888). The PRB was designed to remove americium-241, plutonium-238, plutonium-239,240, strontium-90, nitrate, and perchlorate. Because of their geochemical variability, no single treatment media was optimal for removing all of these COPCs. Consequently, a multiple-layer PRB was designed with multiple treatment zones arranged in series to sequentially remove each of the COPCs. The PRB employs a funnel-and-gate system with a sequential series of four reactive media cells. The funnel consists of a row of sheet piles driven through the alluvium and into the underlying bedrock that directs the alluvial groundwater so that it will flow through the four cells (the gate). The four reactive media cells, ordered by sequence of contact with the groundwater, consist of (1) gravel-sized scoria for colloidal removal; (2) mineral apatite (calcium phosphate) for removing metals and radionuclides; (3) biobarrier cell composed of 65% pecan shells and 10% cotton seed mixed with 25% pea gravel to deplete dissolved oxygen and break down nitrate, perchlorate, and potential RCRA organic compounds; and (4) gravel-sized limestone for pH buffering and anion adsorption. Performance monitoring of the PRB consisted of collecting several rounds of groundwater samples between 2003 and 2005 from the PRB sampling ports and nearby alluvial monitoring wells that were analyzed for major cations and anions and radionuclides (DBS&A 2006, 93888). These data indicated that successful treatment of COPCs occurred in the apatite and biobarrier cells. However, dissolved concentrations of key COPCs measured in the limestone cell and a downcanyon monitoring well—notably, perchlorate, nitrate, and strontium-90—were essentially equivalent to the untreated water upcanyon of the PRB. This pattern of chemical behavior was observed initially under very low alluvial saturation levels in 2003 that created stagnant groundwater flow conditions in the alluvium but also during higher saturation levels in 2004 and 2005 when normal groundwater flow conditions prevailed. Possible explanations for the apparent impaired performance include hydraulic bypass or errors associated with sampling techniques. The performance of the PRB is the subject of ongoing investigations to evaluate these issues.

3.0 SCOPE OF ACTIVITIES

The scope of activities in this report include investigations of sediment, surface water, groundwater, and biota in the Mortandad watershed, as presented in the Mortandad Canyon work plan and subsequent documents (LANL 1997, 96835; LANL 1999, 62777; LANL 2004, 82613; LANL 2005, 89308). These investigations are discussed below.

3.1 Sediment Investigations

The sediment investigations presented in this report focused on characterizing the nature, extent, concentrations, and inventory of contaminants in post-1942 sediment deposits in a series of reaches in the Mortandad watershed. Data from these reaches are used to evaluate potential human health and ecological risks and to identify spatial trends in contamination at a watershed scale, including variations in contaminant concentration and inventory at increasing distances from source areas and temporal trends in contamination. The investigation methods are discussed in Section 4 and Appendix B, Section B-1, of this report; in the "Mortandad Canyon Work Plan" (LANL 1995, 96835; LANL 1999, 62777); and in the canyons core document (LANL 1997, 55622; LANL 1998, 57666).

The scope of this investigation originally included up to 13 investigation reaches in the Mortandad watershed, as presented in Section 7.2.4 of the work plan (LANL 1997, 55622; pp. 7-12–7-30). The scope of work subsequently increased, as discussed below, and a total of 27 investigation reaches have been characterized. Table 3.1-1 lists the sediment investigation reaches and the years in which samples were collected in each reach. Table 3.1-1 also provides abbreviations for reach names included in this report and the approximate length and distance of each reach from the Rio Grande, as well as additional information on the reaches. Figure 3.1-1 and Plate 1 show the location of the investigation reaches within the Mortandad watershed. Note that Pratt Canyon (reach PCYN), a short tributary to Ten Site Canyon below the former TA-35 WWTP, is included in Table 3.1-1, Figure 3.1-1, Plates 1 and 3, and in the physical system conceptual model in Section 7 for completeness but not in the screening assessment in Section 6 or in the risk assessments in Section 8. An evaluation of COPCs and potential risk in Pratt Canyon was completed as part of investigations at TA-35 (LANL 2005, 91867).

During implementation of the work plan in 1998 to 2004, additional investigation areas were added in the Mortandad watershed, and some reaches were subdivided to better identify contaminant sources and to characterize variations in contamination in these canyons. For example, reach TS-2 was subdivided into reaches TS-2 West, TS-2 Central, and TS-2 East, with reach boundaries placed at outfalls from specific SWMUs. Reaches M-3 and M-4 were subdivided to help evaluate variations in contaminant concentrations and inventory related to geomorphic variations in the canyon bottom, although data from all subdivisions of M-3 are evaluated together for risk assessment and also for all subdivisions of M-4. M-3 West consists of the relatively narrow upcanyon portion of M-3; M-3 East consists of the broader downcanyon portion that extends to the confluence with Ten Site Canyon. M-4 West consists of the part of Mortandad Canyon between the Ten Site Canyon confluence and sediment trap #3, M-4 Central consists of the area east of sediment trap #2 where radionuclide concentrations are relatively high, and M-4 East consists of the area farther east where radionuclide concentrations are relatively low.

In 1998, reach M-1 West was added and investigated upcanyon of reach M-1 as shown in the work plan, and the original M-1 was renamed M-1 East. M-1 West is located at the head of Mortandad Canyon just east of Diamond Drive and was investigated to better determine contaminant levels that would be associated with releases from TA-03. In 2001, reach M-2 East was investigated downcanyon of reach M-2 as shown in the work plan, and the original M-2 was renamed M-2 West. M-2 East is located downstream of the easternmost SWMU at TA-35 and was investigated to better determine if TA-35 SWMUs or AOCs have had a measurable impact on sediments in Mortandad Canyon. Investigation of M-2 East was partially in support of planned work at TA-35 under the "Sampling and Analysis Plan for the Middle Mortandad/Ten Site Aggregate" (LANL 2002, 73092). Other objectives of the M-2 East investigation were to obtain additional data on contaminants released from TA-50 and to reduce the length of the nonsampled area between Effluent Canyon and reach M-3. In 2004, reaches E-1 Far West, M-1 Central, and M-5 West were added to the investigation. E-1 Far West is located at the head of Effluent Canyon, upcanyon of the westernmost TA-55 SWMU and was investigated to better determine

relative contributions from TA-48 and TA-55. M-1 Central is located between M-1 West and M-1 East, upcanyon of the westernmost TA-48 SWMU and was investigated to better determine relative contributions from TA-03 and TA-48. M-5 West is located in the middle of a long previously unsampled part of Mortandad Canyon between M-4 and the San Ildefonso Pueblo boundary and was investigated to better determine the eastern extent of recognizable contamination; the previous reach M-5 was renamed M-5 East.

Sediment characterization was also conducted to support the biota investigations according to the study plan presented in the "Mortandad Canyon Biota Investigation Work Plan" (LANL 2005, 89308). This sampling was conducted to provide additional data to support the assessment of potential ecological effects from contamination found in sediment. This characterization included resampling previously sampled sediment layers in some reaches and collecting samples at new locations in other reaches. Details of the methodology are presented in Section B-3 of Appendix B.

3.2 Surface Water and Groundwater Investigations

The water investigations presented in this report focus on characterizing the nature, extent, and concentrations of contaminants in persistent surface water, alluvial groundwater, and perched-intermediate groundwater in and beneath the Mortandad Canyon watershed. Wells extending into the regional aquifer are also considered. Data from these components of the hydrogeologic system are used to evaluate potential human health and ecological risk as well as to identify spatial trends in contamination at a watershed scale, including variations in contaminant concentration at increasing distances from the source areas and as a function of seasonal and annual hydrologic variations. The data are also used to identify temporal trends in contamination. This work involved sampling persistent surface water; drilling and installing monitoring wells and piezometers; sampling new and preexisting groundwater wells; and measuring water level variations in all groundwater sources. Persistent surface water generally refers to effluent-supported flow, standing water in bedrock pools in the channel, snowmelt runoff, and other surface water not related to short-duration stormwater runoff (Section 7.2 further discusses the hydrology of the watershed). Figure 3.2-1 shows the locations of surface and groundwater sites that were sampled as part of this investigation. The investigation methods are discussed in Section 4.2 and Appendix B of this report. The scope of the investigation is described in the "Work Plan for Mortandad Canyon" (LANL 1997, 56835) and the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). The investigation activities described above are discussed in the following sections.

3.2.1 Monitoring Well Installations

Nine alluvial monitoring wells were installed in Mortandad and Ten Site Canyons between 1998 and 2005 to fulfill the requirements of the "Work Plan for Mortandad Canyon" (LANL 1997, 56835) and the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). Well completion diagrams and geologic logs for these wells are provided in the reports "Alluvial Groundwater Monitoring Well Completions, 1994-2001" (LANL 2001, 73307) and "Final MCA Wells, MCB Boreholes, and MCRES Boreholes Completion Report 2004–05 Mortandad Canyon Drilling Program, Los Alamos National Laboratory, Los Alamos, New Mexico, Project 49436" (Kleinfelder 2006a, Appendix 92486). Downhole gamma and induction logs were collected in several boreholes either before plugging and abandonment or before well installation. Other alluvial monitoring wells installed in Mortandad Canyon from 1960 to 1990 for surveillance monitoring were used in these investigations (Purtymun 1995, 45344). In 1994, 24 additional water balance wells were installed in Mortandad Canyon to investigate spatial and temporal changes in alluvial saturation (McLin 1997, 85422). Well completion diagrams and geologic logs for these early wells are compiled in Purtymun (1995, 45344) and McLin (1997, 85422). Figure 3.2-1 and Plate 1 show the locations of the alluvial monitoring wells in the Mortandad Canyon watershed.

Eight intermediate perched monitoring wells and boreholes were installed in Mortandad Canyon in 2001 to fulfill the requirements of the "Work Plan for Mortandad Canyon" (LANL 1997, 56835) and in 2004 and 2005 to fulfill the requirements of the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). Well completion diagrams and geologic logs for these wells are provided in the following reports: "Characterization Well MCOBT-4.4 and Borehole MCOBT-8.5 Completion Report" (Broxton et al. 2002, 76006) and "Final I Wells Completion Report 2004-05 Mortandad Canyon Drilling Program, Los Alamos National Laboratory, Los Alamos, New Mexico, Project 49436" (Kleinfelder 2006b, 92494, Appendix B). Downhole gamma and induction logs were collected in the boreholes either before plugging and abandonment or before well installation. Schlumberger, Inc., collected a more comprehensive suite of geophysical logs in three of the wells (Kleinfelder 2005, 90045; MCOBT-4.4, MCOBT-8.5, and MCOI-5). Figure 3.2-1 and Plate 1 show the locations of intermediate-perched monitoring wells and boreholes in the Mortandad Canyon watershed.

Three additional perched intermediate wells were identified in the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613) as contingent wells that could be installed if results from the seven other intermediate wells indicated the need for additional perched zone characterization. These included a well in upper Ten Site Canyon near R-14 (MCOI-2), a well on the bench south of Mortandad Canyon and south of GS-2 (MCOI-7), and a well on the mesa top south of Mortandad Canyon 1500 ft east of supply well PM-5 (MCOI-9). Intermediate well MCOI-2 was designed to investigate the occurrence of perched groundwater near the TA-35 outfall. Because no perched groundwater was encountered when drilling nearby well R-14, and the regional aquifer has not shown the presence of contaminants, including perchlorate, nitrate, and tritium, MCOI-2 was not considered essential for determining the nature and extent of contaminants in this area and was not discussed. Intermediate well MCOI-7 was not drilled after results from well MCOI-1 indicated there was insufficient groundwater to make a useful well in the narrow part of Mortandad Canyon between Effluent Canyon and TW-8. Intermediate well MCOI-9 was not drilled after results from borehole MCOI-10 indicated that perched groundwater does not extend under the mesa south of Mortandad Canyon.

Four regional groundwater characterization and monitoring wells were installed in Mortandad Canyon; two regional wells were installed in Ten Site Canyon; and one regional well was installed in Cedro Canyon from 1998 to 2005 to fulfill the requirements of the "Work Plan for Mortandad Canyon" (LANL 1997, 56835) and the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). Well completion diagrams and geologic logs for these wells are provided in the following reports: "Revision 1 Well R-1 Completion Report, Los Alamos National Laboratory, Los Alamos, New Mexico" (Kleinfelder 2005a, 90045), "Characterization Well R-13 Completion Report" (LANL 2003a, 76060), "Characterization Well R-14 Completion Report" (LANL 2003b, 76062), "Characterization Well R-15 Completion Report" (Longmire 2001, 70103), "Revision 1 Well R-28 Completion Report, Los Alamos National Laboratory, Los Alamos, New Mexico" (Kleinfelder 2005b, 94042), "Final Completion Report Characterization Well R-33, Los Alamos National Laboratory, Los Alamos, New Mexico" (Kleinfelder 2005c, 94041), "Final Completion Report Characterization Well R-34, Los Alamos National Laboratory, Los Alamos, New Mexico (Kleinfelder 2004, 92199), "Final MCA Wells, MCB Boreholes, and MCRES Boreholes Completion Report 2004-05 Mortandad Canyon Drilling Program" Los Alamos National Laboratory, Los Alamos, New Mexico, Project No. 49436 (Kleinfelder 2006, 92486), and "Final I Wells Completion Report 2004–05 Mortandad Canyon Drilling Program, Los Alamos National Laboratory, Los Alamos, New Mexico, Project No. 49436" (Kleinfelder 2006, 92494). The last two reports listed above are provided in electronic format as part of Appendix B on the attached CD. Schlumberger, Inc., collected a comprehensive suite of geophysical logs in all of the regional well boreholes before well installation Kleinfelder 2005, 90045). TW-8 was installed in Mortandad Canyon in 1960 to determine the hydrologic characteristics of the Mortandad Canyon area and to monitor the regional aquifer for contaminants (Baltz et al.1963, 08402; Purtymun 1995, 45344). The well completion diagram and geologic log for TW-8 are

summarized in Baltz et al. (1963, 08402) and Purtymun (1995, 45344). Historic water-quality data from TW-8 were used with data from the more recent characterization wells to examine spatial and temporal trends in contaminants as part of this investigation report. Figure 3.2-1 and Plate 1 show the locations of the regional groundwater characterization and monitoring wells in the Mortandad Canyon watershed.

3.2.2 Piezometer Installations

Six piezometers were installed in 2004 to fulfill the requirements of the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). The piezometers were installed in Mortandad Canyon to collect information about groundwater flow directions, hydraulic gradients, saturated thicknesses, and extent of saturation in alluvial groundwater west of the confluence with Ten Site Canyon and east of the sediment traps. Well completion diagrams and geologic logs for these piezometers are provided in the report "Final MCA Wells, MCB Boreholes, and MCRES Boreholes Completion Report 2004-05 Mortandad Canyon Drilling Program, Los Alamos National Laboratory, Los Alamos, New Mexico, Project 49436" (Kleinfelder 2006a, 92486). Figure 3.2-1 and Plate 1 show the locations of the piezometers in the Mortandad Canyon watershed.

3.2.3 Surface Water and Groundwater Sampling

Since release of the "Work Plan for Mortandad Canyon" (LANL 1997, 56835), surface water, alluvial groundwater, intermediate-perched groundwater, and regional groundwater samples have been collected in the Mortandad Canyon watershed, supplementing years of data collected by the Laboratory's Environmental Surveillance Program. These investigations were conducted to address characterization requirements presented in the "Work Plan for Mortandad Canyon" (LANL 1997, 56835) and the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613) and to fulfill the requirements of the Laboratory's Environmental Surveillance Program. The "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613) updated the sampling approach initially presented in "Work Plan for Mortandad Canyon" (LANL 1997, 56835) by selecting wells and surface water locations for sampling based on bounding of key potential contaminant sources and collecting data useful for assessing human health and ecological risk.

Based on the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613), sampling of surface water and groundwater was coordinated to provide a "snapshot" in time to evaluate the relationship between constituents in surface water and various groundwater bodies. The snapshot sampling efforts were conducted in 2005 and included two sampling events that were scheduled to coincide with periods of relatively dry and wet hydrologic conditions. Surface water locations were selected from areas where persistent surface water was present. Surface water sampling was also conducted to support the biota investigations (LANL, 2005, 89308), discussed in Section 4.3.

The list of surface water sites and groundwater monitoring wells that were sampled as part of the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613) and the rationale for selecting each sample site are presented in Table 3.2-1. Other wells and surface water locations in the watershed were sampled as part of earlier investigations but are not included in Table 3.2-1. Figure 3.2-1 shows the locations of the sample sites listed in Table 3.2-1. Plate 1 shows those same locations as well as additional monitoring wells, surface water sampling locations, and production wells in the Mortandad Canyon watershed.

3.2.4 Water-Level Measurements

Both manual and automated water-level data have been collected from alluvial monitoring wells, piezometers, intermediate-perched monitoring wells, and regional monitoring wells in the Mortandad watershed. A summary of water-level measurements for wells at LANL, including those in the Mortandad Canyon watershed, is given in the report "Groundwater Level Status Report for 2005, Los Alamos National Laboratory" (Allen and Koch 2006, 93652). Table 3.2-2a shows the list of wells and period of record for the manual water-level data for each well; Table 3.2-2b shows the list of wells and period of record for the automated water-level data for each well. Details of the field methodology and results are presented in Section B-2.2 of Appendix B.

3.2.5 Infiltration Investigation

An infiltration investigation is currently being conducted to fulfill requirements of the "Work Plan for Mortandad Canyon" (LANL 1997, 56835) and the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). The purpose of the infiltration investigation is to constrain the various terms of the water budget to quantify water movement within the deep percolation contaminant transport pathway. These data will support future assessment of groundwater infiltration under varying conditions and for differing source-reduction scenarios (e.g., elimination of TA-50 discharges). To assess flow dynamics within the alluvial aquifer, system vector probes were installed in selected boreholes. Water content and matric potential sensors were also installed in other selected boreholes to analyze vadose-zone dynamics below alluvium. Instrumentation was also installed at locations in the canyon floor to assess percolation rates. Preliminary results for the infiltration study are discussed in Appendix M.

3.2.6 Surface Geophysics

Two surface-based direct-current (DC-) resistivity surveys were conducted in Mortandad Canyon in 2002 and 2004. The 2004 survey fulfills requirements of the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). The objective of the resistivity surveys was to identify regions of higher conductivity beneath the canyon floor that may be related to perched alluvial groundwater and to zones of infiltration in subcropping bedrock units. The surveys were optimized to characterize variations in electrical conductivity in the upper 150 to 200 ft of the vadose zone. Details of the methodology and results for the resistivity surveys are provided in the reports "Pilot Geophysical Studies in Mortandad Canyon, Los Alamos National Laboratory, Los Alamos, NM, Job No. 1171" (Geophex 2002, 94040, Appendix B) and "DC Resistivity Profiling in Mortandad, Ten Site and DP Canyons, Los Alamos National Laboratory, Los Alamos, NM, Job No. 1247" (Geophex 2004, 84540, Appendix B). Locations of the resistivity survey lines are shown in Plate 1.

3.2.7 Characterization Core Holes

Thirteen of 16 planned characterization core holes were installed in Mortandad Canyon in 2004 and 2005 to fulfill the requirements of the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). Two of the planned characterization core holes, MCB-3 and MCB-4, could not be installed because the sites are located in an inaccessible, deeply incised portion of Mortandad Canyon. Access to one site (MCB-13) was denied because it was located in a protected archeological area. Table 3.2-3 describes the characterization boreholes and provides information about their locations, purpose, and depths. Diagrams and geologic logs for these core holes are provided in the report "Final MCA Wells, MCB Boreholes, and MCRES Boreholes Completion Report 2004-05 Mortandad Canyon Drilling Program, Los Alamos National Laboratory, Los Alamos, New Mexico, Project 49436" (Kleinfelder 2006a, 92486, Appendix B). Additional core was collected during installation of intermediate-perched and

regional groundwater monitoring wells, described in Sections 3.2.2 and 3.2.3 above. Figure 3.2-1 and Plate 1 show the locations of the alluvial monitoring wells and piezometers in the Mortandad Canyon watershed.

3.2.8 RES Coreholes

Cores from four boreholes and from one regional aquifer well were collected to compare vertical electrical profiles from the 2002 surface-based DC-resistivity survey with moisture profiles and perched groundwater occurrences detected in boreholes. Table 3.2-3 describes the RES boreholes and provides information about their locations, purpose, and depths. These resistivity boreholes investigations fulfill the requirements of the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). Diagrams and geologic logs for these boreholes are provided in the following reports: "Final MCA Wells, MCB Boreholes, and MCRES Boreholes Completion Report 2004-05 Mortandad Canyon Drilling Program, Los Alamos National Laboratory, Los Alamos, New Mexico, Project 49436" (Kleinfelder 2006a, 92486, Appendix B), "Characterization Well MCOBT-4.4 and Borehole MCOBT-8.5 Completion Report" (Broxton et al. 2002, 76006), and "Revision 1 Well R-28 Completion Report, Los Alamos National Laboratory, Los Alamos, New Mexico" (Kleinfelder 2005b, 94042). Figure 3.2-1 and Plate 1 show the locations of the three RES holes, MCOBT-4.4, and R-28.

3.3 Biological Investigations

The biological investigations presented in this report focused on characterizing the potential for adverse effects of contaminants in post-1942 sediment deposits and surface water on terrestrial and aquatic ecological receptors. These investigations fulfill the general objectives identified in the work plan (LANL 1997, 96835; LANL 1999, 62777) and in the canyons core document (LANL 1997, 55622; LANL 1998, 57666). These investigations build upon the results obtained from sediment and surface water characterization, and the basis for the investigation approach is documented in the "Mortandad Canyon Biota Investigation Work Plan" (LANL 2005, 89308). The investigation methods are discussed in Section 4.3 and Section B-3.0 in Appendix B of this report.

3.4 Deviations from Planned Activities

The sediment, surface water, groundwater, and biota investigations discussed in this report deviated in several respects from that proposed in the original plans. Most of the deviations consisted of additions to scope, such as the investigation of additional sediment investigation reaches that was discussed in Section 3.1. Other deviations resulted when the original work plan (LANL 1997, 56835; LANL 1999 62777) was superseded by later documents, such as the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613) or the "Mortandad Canyon Biota Investigation Work Plan" (LANL 2005, 89308). This section focuses on work proposed in the most recent, applicable document that was not accomplished or that was otherwise changed in a manner that has the potential to negatively affect the scope of this investigation.

Plans for drilling 9 alluvial wells, 16 characterization boreholes, 3 resistivity boreholes, and 7 intermediate wells were described in the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). Four regional wells (R-1, R-28, R-33, and R-33) were also described in that plan; details of activities and well construction for these holes to the regional aquifer are described in dedicated borehole completion reports for each well (Kleinfelder 2004, 92199; Kleinfelder 2005a, 90045; Kleinfelder 2005b, 94042; Kleinfelder 2005c, 94041). Exceptions and modifications to the other alluvial wells as well as characterization boreholes, resistivity boreholes, and intermediate wells are detailed in Table 3.4-1. Among the alluvial wells installed, MCA-4 provided an adequate sample only for the first round of

sampling. Nearby, alluvial well MCO-2 has been sampled in instances where an adequate sample could not be obtained from MCA-4 (see Table 3.2-1), and data from both wells have been used to represent the alluvial system in Effluent Canyon upstream of the TA-50 outfall.

The biota investigation was completed as planned with several exceptions. It was planned to analyze earthworms used in the earthworm toxicity test for COPECs, but the analytical laboratory instead disposed of these samples, and analyses were not obtained. It was planned to collect aquatic invertebrates using a Hess sampler for taxonomic identification and comparison to NMED's draft "Stream Condition Index for New Mexico Wadeable Streams;" but flow was insufficient to use the Hess sampler. It was also planned to submit aquatic invertebrates obtained with a dip net for radiological analyses, but insufficient invertebrate mass was obtained for these analyses.

4.0 FIELD INVESTIGATIONS

Field investigations in the Mortandad watershed included investigations of sediment, surface water, groundwater, and biota. The approaches and methods of these investigations are briefly discussed in the following subsections. A more detailed discussion of the methods and the results of the field investigations is presented in Appendix B.

4.1 Sediment

Sediment investigations in the Mortandad watershed included detailed geomorphic characterization and sediment sampling in a series of discrete reaches, following the general process described in the NMED-approved work plan and canyons core document (LANL 1997, 55622; LANL 1997, 56835; LANL 1998, 57666; LANL 1999, 62777). The geomorphic characterization in most reaches included preparing a detailed geomorphic map delineating the horizontal extent of geomorphic units with varying physical characteristics, contaminant concentrations, and/or age. Field radiological screening measurements were used to help delineate geomorphic units in reaches where the levels of radionuclide contamination in post-1942 sediment exhibited higher levels of radiation than nearby pre-1943 sediment. The geomorphic characterization also included measuring the thicknesses of potentially contaminated post-1942 sediment deposits to estimate the volume of contaminated sediment and the contaminant inventory in each reach. Several methods were used to identify the bottom of post-1942 sediment deposits, including determining the depth of buried trees and associated buried soils, and noting the presence or absence of materials imported to the watershed after 1942 (e.g., quartzite gravel, plastic).

Field data on the volume and radiation levels in the different geomorphic units in a reach were used to help allocate samples for analysis at off-site laboratories. In most reaches, samples were collected in multiple phases, and analytical results from initial sampling phases were used to help guide subsequent sampling. Section B-1 of Appendix B includes a more detailed discussion of the investigation methods. All analytical results of the sediment sampling incorporated in this investigation report are presented in Appendix C on a CD included with this report.

Plates 2 to 5 present geomorphic maps for reaches in the Mortandad watershed and sample locations, field radiological measurement locations, and stratigraphic description locations within these reaches. The horizontal extent of contaminated or potentially contaminated sediment deposits in each reach is delineated by the extent of the channel ("c") and floodplain ("f") units in these maps. Section B-1 of Appendix B includes field investigation results, including field radiological screening results.

4.2 Surface Water and Groundwater

The surface water and groundwater investigations in the Mortandad Canyon watershed are designed to define the nature and extent of contamination, to identify the physical and chemical processes controlling contaminant distributions, and to identify the transport pathways that could result in potential human health and ecological risk. This work includes sampling persistent surface water; drilling and installing monitoring wells and piezometers; sampling new and preexisting groundwater wells; and measuring water level variations in all groundwater sources. In addition, core was collected to characterize the distribution contaminants and moisture in rock units of the upper vadose zone. The investigation methods are discussed in Appendix B of this report. The scope of the investigation is described in the "Work Plan for Mortandad Canyon" (LANL 1997, 56835) and the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613).

4.2.1 Monitoring Well Installations

Nine alluvial wells, eight intermediate wells, and seven regional wells were installed to fulfill the requirements of the "Work Plan for Mortandad Canyon" (LANL 1997, 56835) and the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). Detailed well completion reports describe the investigation methods, well completion diagrams, geologic logs, and borehole geophysical logs for these wells. These well completion reports are described in Section 3.2.1 of this investigation report. Table 3.2-1 provides information about the location, purpose, and depth of these wells.

4.2.2 Piezometer Installations

Piezometers were installed to evaluate groundwater flow directions, hydraulic gradients, saturated thicknesses, and extent of saturation in the alluvial groundwater system. The piezometers were installed at two locations, each containing three closely spaced piezometers to monitor water levels in the alluvial system. The piezometers consist of 0.8-in. I.D. (1.1-in. O.D.) PVC casings coupled to 1.4-in. O.D. prepacked screens surrounded with 10/20 sand. Slot sizes are 0.01 in., and the screens are 6 in. long. Slug tests were conducted in the completed piezometers.

One group of piezometers consisting of MCA-3a, MCA-3b, and MCA-3c (Figure 3.2-1) was installed in Mortandad Canyon west of the confluence with Ten Site Canyon. MCA-3a and MCA-3c were installed in the same borehole and are screened across the lower and upper parts of the alluvial system, respectively. MCA-3b was installed in an adjacent borehole, and it is screened across the middle portion of the alluvial system. Slug tests were conducted in the three piezometers.

The second group of piezometers consisting of MCA-3d, MCA-3e, and MCA-3f (Figure 3.2-1) was installed east of the sediment traps, near the eastern limit of persistent alluvial saturation. The three piezometers were installed in a single borehole to measure water levels in the upper (MCA-3f), middle (MCA-3e), and lower (MCA-3d) parts of the alluvial system. Slug tests were conducted in MCA-3d.

4.2.3 Surface Water and Groundwater Sampling

As described in Section 3.2, sampling of persistent surface water, alluvial groundwater, perched-intermediate groundwater, and regional groundwater was coordinated to provide a snapshot in time to evaluate the relationship between constituents in surface water and various groundwater bodies. Snapshot sampling was conducted in 2005 and included two sampling events that were scheduled to coincide with periods of relatively dry and wet hydrologic conditions. The first round of samples was collected in late April to mid-June during relatively dry conditions. The second round of samples was

collected in mid-August to mid-September during wet conditions, coinciding with the summer monsoon season. Samples were collected at designated locations described in the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). Under this work plan, alluvial groundwater monitoring wells and surface water locations were sampled concurrently (typically within a period of less than 6 weeks) to obtain a comprehensive and current data set and a synoptic perspective of the hydrology and contaminants present in water within the watershed. A key objective was to characterize potential contaminant variability associated with variations in surface water and alluvial groundwater conditions. Sampling surface water and alluvial groundwater concurrently also allows for evaluating the relation between surface water and alluvial groundwater quality. Sampling was attempted at designated locations in each of the two sampling rounds, and samples were collected if sufficient water was present. Some additional surface water stations and wells, in addition to the designated locations required in the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613), were added to the rounds of snapshot sampling to replace dry sample locations and to provide more comprehensive water quality data for the watershed. Table 4.2-1 summarizes the sampling conducted during the two rounds required under the work plan, as well as other sampling conducted as part of Laboratory facility-wide surveillance sampling and during early RFI sampling in the watershed conducted under the "Work Plan for Mortandad Canyon" (LANL 1997, 56835).

Most of the surface water and groundwater samples were collected in accordance with ER Project standard operating procedures (SOPs), and a few were collected as part of annual surveillance monitoring using Water Quality and Hydrology (WQH) procedures. The procedures for sample collection are described in Appendix B, and the analytical results of the sampling are discussed in Appendix C and provided on a CD included with this report. With the exception of R-33, which had equipment problems, a water-level measurement was collected from each well before purging for a sampling event. The water-level measurements associated with sampling are also presented in Appendix F. Water-quality field parameters including pH, specific conductance, temperature, and turbidity were measured for each surface water and groundwater sample collected. Measurements of field parameters were taken as part of groundwater sampling to evaluate the effectiveness of purging. Field parameters data were also collected for surface water and groundwater samples to provide data potentially useful for evaluating contaminant variability. These field parameters were logged in a water-quality stabilization record form for each sample and are presented in tables in Section B-2 of Appendix B. The methodology for collecting field parameters and results is also described in Section B-2.0.

4.2.4 Water-Level Measurements

Historical and new water-level data were compiled for alluvial, intermediate, and regional wells in Mortandad Canyon. These data, which included both manual and automated measurements, allow interconnections between groundwater bodies to be assessed by comparing water-level responses with storm events and seasonal variations in precipitation. Water-level data are also collected to determine hydraulic gradients within groundwater bodies and to assess hydraulic conductivity. Details of the field methodology and results are presented in Section B-2.2 of Appendix B.

Systematic manual water-level measurements for selected alluvial observation wells (MCO series) began in 1960 to document seasonal water-level fluctuations in the alluvial groundwater system. In 1994, water balance wells were installed in Mortandad Canyon to investigate spatial and temporal changes in alluvial saturation (McLin et al. 1997, 85422). Manual water-level measurements were taken in selected water balance wells in 1995 and 1996 and automated, high-frequency water-level data were collected using pressure transducer probes from 1997 to 2005. Automated pressure transducer probes were also placed in the alluvial wells and piezometers installed in 2004 and 2005.

Automated pressure transducers were also installed for acquisition of water levels in intermediate-perched groundwater. An automated pressure transducer has collected intermittent water-level data for intermediate-perched monitoring well MCOBT-4.4 since 2002. Automated pressure transducer probes were also placed in wells MCOI-4, MCOI-5, MCOI-6, and MCOI-8.

Water-level data for the regional aquifer wells includes both manual and automated water-level measurements. At first, water-level measurements were collected manually from the regional aquifer wells during water sampling events. In late 2004 and early 2005, automated pressure transducer probes were installed in all but one of the regional aquifer wells installed for the "Work Plan for Mortandad Canyon" (LANL 1997, 56835) and the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613). R-33 is the only regional well without an automated transducer because there is an equipment problem with the multiport sampling system. TW-8 has the longest period on record of all the regional aquifer wells. An automated pressure transducer was installed in TW-8 in 1992 and it has collected water-level data intermittently since then.

4.2.5 Infiltration Investigation

The "Work Plan for Mortandad Canyon" (LANL 1997, 56835) specifies that field-based work is needed to quantify the movement of water through the vadose zone (including the alluvial aquifer system). The Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613) also contains a requirement to assess subsurface water movement in the canyon. Therefore, the Mortandad Canyon infiltration study was implemented to understand spatial and temporal variability of the rates of water movement above, below, and within the alluvial aquifer system and to determine unsaturated zone fluxes in selected locations where no current alluvial water exists. Multiple approaches were used to address these goals, and these are described from shallowest to deepest below. Preliminary results of the infiltration investigation are discussed in Appendix M.

One potential pathway for contaminant transport and recharge in the canyon is percolation through the bottom of the streambed. To quantify this loss, instrumentation was installed at nine locations in the canyon to collect high-time-resolution temperature profiles down to about 180 cm below the stream channel. This method uses heat as a tracer to determine downward fluxes (Constantz et al. 2003, 94090). From the temperature data, the frequency and duration of streambed infiltration events can be determined and downward fluxes can be estimated.

Borehole data from Mortandad Canyon shows that the extent of perchlorate and nitrate contamination extends laterally well beyond the incised channel. Thus, it is important to quantify percolation in the floodplains and terraces as well as the channel. Twelve fiberglass wicktype flux meters were installed at various canyon locations (away from the channel) to measure downward unsaturated flow rates at a depth of approximately 100 cm below the canyon floor. At two of these locations, paired matric potential and water content sensors were also installed. These sensors are used to quantify downward fluxes that are below the detection level of the flux meters and also to quantify rates and durations of upward flux events.

Vector probes were installed in five boreholes (MCB-5, MCB-6, MCB-9, MCB-14, and MCRES-2) to assess flow dynamics within the alluvial aquifer system (see www.hydrotechnics.com for more information about the probes). The vector probes were emplaced in selected MCB and MCRES holes at depths thought to represent the most transmissive alluvial aquifer flow zones identified during drilling (typically above the alluvium/tuff contact). The vector probes provide quantitative information on flow rates and directions within the alluvial aquifer system and how they might vary with time.

A series of volumetric water content and matric potential sensors were also installed in six boreholes (MCB-2, MCB-7, MCB-8, MCB-11, MCB-16, and MCRES-4) below the alluvium (within the tuff) to quantify fluxes in bedrock units. These sensors provide data on the spatial and temporal variability of deep fluxes within the canyon and help constrain recharge fluxes to the deeper intermediate-perched aquifer zone in the canyon.

4.2.6 Surface Geophysics

A DC-resistivity survey was conducted in Mortandad Canyon in summer 2002 to determine whether this geophysical method was an effective and appropriate means to identify zones of saturation and moisture within the alluvial and upper vadose zone systems (Geophex 2002, 94040, Appendix B). Geophysical survey lines are shown in Figure 4.2-1. Geophex conducted the geophysical surveys and prepared a summary report that was submitted to NMED on March 26, 2003 (Geophex 2002, 94040). Nine DC resistivity profiles were compiled in the middle portion of Mortandad Canyon. One profile was collected continuously along the centerline of the canyon from a point upstream of the PRB to a point near well R-13, a distance of 2830 m (9290 ft) to the east (Figure 4.2-1). The remaining profiles consisted of a series of transects across the canyon at selected locations. Profile depths of penetration varied according to the length of the line and the spacing of electrodes. In the upper reaches of the canyon, the shortest profile penetrated approximately 6 to 9 (20 to 30 ft) below ground surface (bgs). The longest profiles imaged to depths of over 60 m (200 ft) bgs.

A second DC resistivity survey was conducted by Geophex in December 2003 to cover additional parts of upper Mortandad Canyon that were not included by the 2002 survey (Geophex 2003, 84540). Geophysical survey lines are shown in Figure 4.2-1. One DC resistivity profile was completed for a distance of 1800 m (5904 ft) along the centerline of upper Mortandad Canyon from a point upstream of the PRB to the confluence with Effluent Canyon. A second profile was compiled for a distance of 220 m (722 ft) along the centerline of lower Effluent Canyon. A third profile was completed for a distance of 475 m (1558 ft) along the centerline of lower Ten Site Canyon from a point where the canyon becomes broad and flat eastward to the confluence with Mortandad Canyon. A fourth line is a north-south transect that extends 192 m (631 ft) across the mouth of Effluent Canyon into Mortandad Canyon.

4.2.7 Characterization Core Holes

A list of the characterization core holes and information about their locations, purpose, and depths are provided in Table 3.2-3. These core holes were drilled to depths ranging between 25 to 87 m (84 and 284 ft) in Effluent, Mortandad, and Ten Site Canyons. Cores collected from the boreholes were used to determine moisture content, adsorption capacity, and the nature and the extent of contamination in the alluvium and upper portions of the Bandelier Tuff/Cerro Toledo interval. Geologic and hydrologic data from these core holes also provide site-specific data for modeling hydrological and geochemical-contaminant transport mechanisms.

Core was collected using hollow-stem auger methods without the use of drilling fluids. Cores were collected from all major stratigraphic units, including the alluvium at a nominal sample interval of 3 m (10 ft) to determine contaminant distributions in the upper vadose zone. Samples were containerized to prevent moisture loss and were analyzed for moisture content, metals, anions, stable isotopes, and radionuclides. Where feasible, borehole gamma and induction logs were collected in uncased portions of the boreholes. In general, the core holes were plugged and abandoned with bentonite after reaching total depth. However, five of the boreholes were instrumented before being backfilled as part of infiltration investigations as described in Section 4.2.5.

Analytical data for cores are discussed in Section 7.2.2. Appendix D contains plots of contaminated profiles in cores and in pore waters extracted from cores. Appendix B presents moisture profiles for the core holes.

4.2.8 RES Coreholes

The 2002 DC resistivity survey suggested that various moist zones might be mapped by the electrical profiles. The degree of saturation or moisture within these zones is not known and can only be confirmed by measuring the moisture content in the boreholes. The high resistivity areas are inferred to be either "dry" or "dryer" unconsolidated sediments or dry bedrock, for example, in the upper portions of the Bandelier Tuff. The dry bedrock zones vary in elevation across the deeper portions of the profiles. Vertical zones of lower resistivity appear to cut through dry bedrock zones and extend to greater depths in certain areas. These features are interpreted to be either "moist" or clay-rich fracture zones within the dryer bedrock.

Core holes MCRES-2, MCRES-3, MCRES-4 (Figure 3.2-1) targeted areas of low and high resistivity identified in the 2002 resistivity survey to evaluate the relationship between the electrical profiles and in situ moisture and physical property measurements determined from core. Core holes MCRES-3 and MCRES-4 are located near TW-8 in resistive and conductive zones, respectively. Near the confluence of Mortandad and Ten Ste Canyons, core was collected from MCRES-2 for comparison to the moisture profile collected from existing well MCOBT-4.4. The 2002 DC resistivity profile suggests that MCOBT-4.4 was drilled in an area where high conductivity extends to greater depths than at MCRES-2. Core was also collected from the upper 45 m (150 ft) of R-28 to evaluate conductivity data from a spot yet farther downcanyon. At R-28, a sharp electrical boundary at 24-m (80-ft) depth separates a conductive zone above from a resistive zone below. Core samples collected at a nominal interval of 3 m (10 ft) were analyzed for moisture content, grain size, porosity, and clay content.

4.3 Biota

Biological data were collected to evaluate the potential for adverse ecological effects from contaminants in sediment and surface water. Biota investigations in the Mortandad watershed included a range of activities, as presented in the NMED-approved "Mortandad Canyon Biota Investigation Work Plan" (LANL 2005, 89308). Field investigations included studies of bird nest boxes, plant and bird surveys, collection of sediment samples for earthworm toxicity tests, seedling germination tests, aquatic toxicity tests, and collection of water samples for algae toxicity tests. The nest box study included adding nest boxes to an existing network, collecting data on occupancy, and collecting samples of eggs and insects for laboratory analyses. These activities are discussed in more detail in Section 8.1 and Section B-3.0 of Appendix B.

5.0 REGULATORY CRITERIA

This section provides information on the regulatory context, human health screening levels, ecological screening values, and water standards and screening levels.

5.1 Regulatory Context

Regulatory requirements governing the Laboratory's canyons investigations are discussed in Section 1.4 of NMED-approved canyons core document (LANL 1997, 55622, LANL 1998, 57666). In particular, these investigations address requirements of the Laboratory's Hazardous Waste Facility Permit (Module VIII) under RCRA, including "the existence of contamination and the potential for movement or transport to or

within Canyon watersheds" (EPA 1990, 1585; EPA 1994, 44146). RCRA and the New Mexico Hazardous Waste Act (NMHWA) regulate releases of hazardous wastes and hazardous waste constituents. DOE Order 5400.1, "General Environmental Protection Program," establishes requirements for managing residual radioactivity at DOE facilities.

As a result of the operational history of sites in the Mortandad watershed, this investigation addresses both radioactive and hazardous components. NMED has authority under the NMHWA over the cleanup of hazardous wastes and hazardous constituents, while DOE has authority over the cleanup of radioactive contamination. Radionuclides are regulated under DOE Order 5400.5, "Radiation Protection of the Public and the Environment," and DOE Order 435.1, "Radioactive Waste Management."

The regulatory requirements for conducting investigations in the Mortandad watershed are incorporated into Module VIII through work plans approved by NMED. The approved work plans include the "Work Plan for Mortandad Canyon" (LANL 1997, 56835; LANL 1999, 62777), the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613), and the "Mortandad Canyon Biota Investigation Work Plan" (LANL 2005, 89308). Corrective actions at the Laboratory are subject to the Consent Order, which contains general requirements and those specific to the Mortandad watershed (Section IV.B.2, "Mortandad Canyon Watershed"). The Consent Order was issued pursuant to NMHWA, New Mexico Statutes Annotated (NMSA) 1978 § 74-4-10 and the New Mexico Solid Waste Act (NMSWA), NMSA 1978, § 74-9-36(D). The requirements of the Consent Order now supersede those of Module VIII.

Surface water discharges that are subject to a permit under Section 402 of the federal Clean Water Act, including stormwater discharges, are not regulated under the Consent Order. Requirements for stormwater monitoring are contained in a Federal Facility Compliance Agreement/Administrative Order (FFCA/AO) between EPA and DOE.

The assessments in this report are primarily risk based for all media and contaminants. Surface water and groundwater standards are used to support the assessment of nature and extent of contamination in canyons media. Concentrations of chemicals and radionuclides are compared with various risk-based screening levels, which are described in Sections 5.2 and 5.3. Applicable water standards are discussed in Section 5.4.

5.2 Human Health Screening Levels

In Section 6, soil screening levels (SSLs) for inorganic and organic chemicals and screening action levels (SALs) for radionuclides are media-specific concentrations derived for residential exposures. If environmental concentrations of contaminants are below SALs or SSLs, then the potential for adverse human health effects is considered highly unlikely. For sediment nonradionuclide COPCs with carcinogen or noncarcinogen endpoints, SSLs from revision 4.0 of NMED guidance (NMED 2006, 92513) were used if available. If values were not available from NMED then residential screening values were obtained from EPA Region 6 or EPA Region 9. The SSLs for noncarcinogens are based on a hazard quotient (HQ) of 1.0. The SSLs for carcinogens are based on a cancer risk level of 10^{-5} (10E-5). For nonradionuclide COPCs without NMED SSLs, approved surrogate values were used (NMED 2003, 81172). SALs for radionuclides were obtained from Laboratory guidance (LANL 2005, 88493). The radionuclide SALs for sediment have a target dose limit of 15 millirem per year (mrem/yr), which is consistent with guidance from DOE (DOE/AL 2000, 67153).

Human health screening levels for water are EPA Region 6 Human Health Medium Specific Screening Level (HHMSSL) tap water screening levels for carcinogens and noncarcinogens and DOE-Derived Concentration Guidelines (DCG) for radionuclides. The screening levels for carcinogens and

noncarcinogens in water are based on the same HQ and cancer risk levels as the SSLs. The screening values for radionuclides in groundwater were calculated based on a target dose limit of 4 mrem/yr, which is the radiation dose limit for a public drinking water supply in DOE Order 5400.5, "Radiation Protection of the Public and the Environment." The screening values for radionuclides in surface water were calculated based on a target dose limit of 100 mrem/yr, which is the radiation dose limit for the general public from all sources in DOE Order 5400.5, "Radiation Protection of the Public and the Environment."

Additional information regarding the potential for human health risks from affected media in the Mortandad watershed is provided in Section 8.2.

5.3 Ecological Screening Levels

Ecological screening levels (ESLs) are used to determine chemicals of potential ecological concern (COPECs) for water and sediment data. The document "Screening Level Ecological Risk Assessment Methods, Rev. 2" (LANL 2004, 87630) contains information about how ESLs are derived. ESLs are developed for a suite of receptors designed to represent individual feeding guilds, such as invertivorous mammal or carnivorous bird. Receptors such as robins and kestrels are modeled with multiple diets to represent multiple feeding guilds. The representative concentration of each COPC was compared with ESLs from the ECORISK Database Versions 2.1 (LANL 2004, 87386) or 2.2 (LANL 2005, 90032).

Additional information regarding the potential for ecological risks from affected media in the Mortandad watershed is provided in Section 8.1.

5.4 Water Standards and Screening Levels

COPCs are identified by comparing concentrations in water with applicable water standards and screening values. All surface water sampling locations in the Mortandad watershed are designated ephemeral. Water standards that apply to ephemeral surface waters (not including stormwater runoff) include the following.

- Aquatic Acute Life (New Mexico Water Quality Control Commission [NMWQCC] Acute Aquatic Life criteria, New Mexico Administrative Code [NMAC] 20.6.4.900 (H), (I), and (J), effective July 2005. Hardness-dependent criteria are calculated using 100 mg/L $CaCO_3$.)
- Livestock Watering (NMWQCC Livestock Watering criteria, NMAC 20.6.4.900 (F) and (J), effective July 2005)
- Wildlife Habitat (NMWQCC Wildlife Habitat criteria, NMAC 20.6.4.900 (G) and (J), effective July 2005)
- Human Health Persistent (NMWQCC human health criteria for persistent toxic pollutants, NMAC 20.6.4.900 (J), effective July 2005. Human health criteria for toxic, carcinogenic, and persistent pollutants only)

Concentrations of radionuclides in surface water were compared with the following values to identify COPCs:

- DCG based on 100 mrem/yr

To identify COPCs in groundwater, comparisons to the lowest of the following standards were performed:

- Human Health (NMAC 20.6.2.3103.A: Human health standards)

- Other Standards for Domestic Water (NMAC 20.6.2.3103.B: Other standards for domestic water supply)
- EPA maximum contaminant levels (MCLs)

If none of the above standards exist for an analyte, the following values were compared with concentrations in groundwater to identify COPCs:

- DCG based on 4 mrem/yr
- EPA Region 6 HHMSSLs for tap water (EPA 2005, 91002)

Stormwater discharges are regulated under the federal Clean Water Act, and no applicable standards for stormwater are under the Consent Order. For informational purposes, available stormwater monitoring data for the Mortandad watershed are compared with water screening action levels (wSALs) established under the FFCA/AO. The wSAL for an analyte is designated as the lowest numeric criterion of the applicable NMWQCC water quality criteria (WQC) established in State of New Mexico Standards for Interstate and Intrastate Surface Waters (NMAC 20.6.4), if one exists. The wSALs for each contaminant are determined in stepwise fashion by evaluating, in the following order

- requirements for any FFCA-monitored segment that is included in a classified water of the state in 20.6.4.101 through 20.6.4.899 NMAC;
- requirements for any FFCA-monitored surface water that is not included in a classified water of the state in 20.6.4.101 through 20.6.4.899 NMAC; or
- *Federal Register,* EPA. Multi-Sector General Permit benchmark values for Sector K, Hazardous Waste Treatment, Storage, or Disposal Facilities.

Classified waters of the state that are described in NMAC 20.6.4.101 through 20.6.4.899 have segment-specific designated uses. Nonclassified surface waters are described as ephemeral (NMAC 20.6.4.97), intermittent (NMAC 20.6.4.98), or perennial (NMAC 20.6.4.99), each of which has designated uses. The designated uses for surface water are associated with use-specific WQC, including numeric criteria. Stormwater in the Mortandad watershed is described as nonclassified, ephemeral; the relevant list of wSALs and their bases are provided in Appendix C.

6.0 CANYONS CONTAMINATION

This section describes the methodology and results of analytical data screening assessments for samples collected to identify COPCs in sediment, surface water, groundwater, and core samples. Identifying COPCs forms the basis for evaluating contamination in canyons media. All COPCs identified in this section are evaluated in human health risk assessments in Section 8.2 and have been considered in developing the measures evaluated in the baseline ecological risk assessment in Section 8.1. A subset of these COPCs is discussed in the conceptual model in Section 7. Section 6.1 briefly describes how the data were prepared for the screening processes. Section 6.2 presents the screens for sediment, Section 6.3 presents the screens for surface water and groundwater, and Section 6.4 presents the screens for core samples. The term “sediment” includes all post-1942 sediment deposits in the canyon bottoms, including deposits in abandoned channels and floodplains as well as in active stream channels; therefore, sediment includes alluvial soils as defined in some other studies.

6.1 Data Preparation

The data used in the following assessments were obtained from the Environmental Restoration Database (ERDB) and the Water Quality Database (WQDB) (on DVD as Attachment 1). All data are presented in Appendix C, Analytical Results (on CD).

Certain analytical results are not evaluated in the screens and subsequent risk assessments for the following reasons.

- Semivolatile organic compound (SVOC) results from samples analyzed by a volatile organic compound (VOC), PAH, or high explosives (HE) analytical method. These duplicate results are excluded from the screen because the VOC, PAH, and HE analytical methods provide lower detection limits than the SVOC method.
- Field duplicate results. These results are from samples obtained for quality assurance/quality control (QA/QC) purposes and not as primary characterization data.
- Isotopic thorium results by gamma spectroscopy. For sediment, these results are excluded because gamma spectroscopy analysis yields results that cannot be directly compared with sediment background values (BVs).
- Results from composite sediment samples collected to support ecological risk studies. These composite samples are used to support the ecological risk assessment in Section 8.1, but they cannot be compared with the other samples in this investigation; therefore, they have been excluded from the screens and from the subsequent human health risk assessments.
- Samples collected from material that has since been excavated (indicated by a "Y" in the excav_flag field in the Appendix C analytical results tables). These data are not representative of current site conditions, so they are excluded from the COPC identification process. However, these data are used in the conceptual site model in Section 7.1.
- Results from water samples collected before 2000. These results are not used in the COPC screens because in many instances the data do not have accompanying data packages for validation and are considered screening level. Also, concentrations in older data are not representative of current site conditions. However, pre-2000 data are used in the trend analyses presented in the conceptual site model in Section 7.2.

6.2 Contaminants in Sediment

This section presents the process for screening analytical results obtained from sediment samples collected in the Mortandad watershed. Samples collected and analyses performed by the analytical laboratories are presented in Table C-2.0-1 in Appendix C. Sample locations are presented in Plates 2 through 5. Analytical results were screened to develop a list of COPCs, as presented in Section 6.2.1.

6.2.1 Identification of Sediment COPCs

Sediment COPCs are identified by a screening process that includes comparing the maximum chemical concentrations by reach with Laboratory-specific sediment BVs (presented in LANL 1998, 59730). Analytes are retained as COPCs using rules specific to the class of analyte. This process is discussed below.

For inorganic chemicals, an analyte is retained as a COPC in a reach if

- the analyte has a BV and a detected or nondetected result in the reach exceeds the BV, or
- the analyte does not have a BV, but at least one detected result is in the reach.

For radionuclides, an analyte is retained as a COPC in a reach if

- the analyte has a BV and at least one detected result in the reach exceeds the BV, or
- the analyte does not have a BV but has at least one detected result in the reach.

There are no BVs for organic chemicals, and retaining an organic chemical as a COPC is based solely on detection status. For organic chemicals, an analyte is retained as a COPC in a reach if there is at least one detected result in the reach.

A total of 38 inorganic chemicals, 74 organic chemicals, and 17 radionuclides were retained as COPCs in sediment in the Mortandad watershed. Maximum sample results in each reach for these COPCs are presented in Tables 6.2-1, 6.2-2, and 6.2-3 for inorganic chemicals, organic chemicals, and radionuclides, respectively.

6.2.2 Comparison of Sediment COPC Concentrations to Residential SSLs and SALs

Maximum concentrations (including detection limits for inorganic chemicals) of sediment COPCs in each reach were compared with residential SSLs for inorganic and organic chemicals or residential SALs for radionuclides to identify which are most important for understanding potential human health risk. A total of three inorganic COPCs, two organic COPCs, and nine radionuclide COPCs have maximum concentrations exceeding residential SSLs or SALs in the Mortandad watershed, and these are included in the conceptual model for sediment in Section 7.1. These COPCs are highlighted in gray in Tables 6.2-1, 6.2-2, and 6.2-3.

6.3 Contaminants in Surface Water and Groundwater

This section presents the process for screening surface water and groundwater sample results from the Mortandad watershed. Samples collected and analyses performed by the analytical laboratories are presented in Table C-2.0-2 in Appendix C. Sample locations are presented in Plates 2 through 5. Analytical results from water samples were screened to develop a list of COPCs, as presented in Section 6.3.1.

6.3.1 Identification of Surface Water and Groundwater COPCs

There are no BVs for water data, and COPCs are identified by a screening process that is based only on the detection status. This process is performed for groups of data defined by field preparation (filtered or nonfiltered samples) and analyte type (inorganic chemicals, organic chemicals, and radionuclides). No organic chemical analyses were obtained from filtered water samples. An analyte is retained as a COPC for a location if the chemical has at least one detected result.

A total of 62 inorganic chemicals, 42 organic chemicals, and 16 radionuclides were retained as COPCs in surface water and/or groundwater in the Mortandad watershed. Maximum sample results at each sample location for these COPCs are presented in Tables 6.3-1 through 6.3-5.

6.3.2 Comparison of Water COPC Concentrations to Standards

Maximum detected concentrations of water COPCs by location and field preparation were compared with applicable water standards, as discussed in Section 5, to identify which are most important from a regulatory perspective. A total of six inorganic chemicals and one radionuclide have maximum detected concentrations in intermediate-depth or regional groundwater exceeding groundwater standards and are

discussed in the conceptual model for water in Section 7.2. COPCs exceeding standards are highlighted in gray in Tables 6.3-1 through 6.3-5.

6.4 Contaminants in Core Samples

This section presents the process for screening analytical results obtained from core samples collected in the Mortandad watershed. Samples collected and analyses performed by the analytical laboratories are presented in Table C-2.0-3 in Appendix C. Sample locations are presented in Plates 2 through 5. Analytical results were screened to develop a list of COPCs, as presented in Section 6.4.1.

6.4.1 Identification of Core COPCs

COPCs in core samples are identified by a screening process that includes comparing the maximum inorganic chemical or radionuclide concentrations by location and geologic unit with Laboratory-specific BVs presented in LANL (1998, 59730). Analytes are retained as COPCs using rules specific to the class of analyte. This process is discussed below.

For inorganic chemicals, an analyte is retained as a COPC in a borehole if

- the analyte has a BV and a detected or nondetected result in the geologic unit that exceeds the BV, or
- the analyte does not have a BV, but there is at least one detected result in the geologic unit.

For radionuclides, an analyte is retained as a COPC in a borehole if

- the analyte has a BV and at least one detected result in the geologic unit exceeds the BV, or
- the analyte does not have a BV but has at least one detected result in the geologic unit.

A total of 22 inorganic chemicals and 8 radionuclides were retained as COPCs in core samples in the Mortandad watershed. Maximum sample results at each borehole for these COPCs are presented in Tables 6.4-1 and 6.4-2 for inorganic chemicals and radionuclides, respectively. No organic chemical analyses were obtained from core samples, so there are no organic COPCs identified in the boreholes.

6.4.2 Comparison of Core COPC Concentrations to Residential SSLs and SALs

Maximum concentrations (including detection limits for inorganic chemicals) of COPCs by borehole and geologic unit were compared with residential SSLs for inorganic chemicals or residential SALs for radionuclides for purposes of comparison with results in other media. Only one inorganic COPC, iron, has a maximum result from a borehole exceeding residential SSLs. This result is highlighted gray in Table 6.4-1. No radionuclides exceeded residential SALs.

6.5 Summary

Table 6.5-1 presents a summary of the COPCs in sediment, water, and core samples collected from the Mortandad watershed to allow comparisons between media. Table 6.5-1 also indicates which COPCs have maximum results in the watershed exceeding SSLs, SALs, and standards.

7.0 PHYSICAL SYSTEM CONCEPTUAL MODEL

This section discusses aspects of the physical system conceptual model that are relevant for understanding the nature, sources, extent, fate, and transport of contaminants in the Mortandad watershed. The discussion on contaminants focuses on COPCs that are shown to be most important for evaluating potential present-day human health risk based on the comparisons with SALs, SSLs, and standards in Section 6 and that represent known contaminant releases into the watershed. These COPCs are included in evaluations of potential human health risk in Section 8.2. This section also includes discussion of other COPCs that were identified as study design COPECs and are relevant for evaluating potential present-day ecological risk. Some additional COPCs are discussed to provide insights into sources and trends of contaminants historically or otherwise important in the watershed, including some COPCs that were detected on San Ildefonso Pueblo land and that are relevant for understanding the downcanyon extent of Laboratory-derived contamination. As used in this section, "contaminants" refers to COPCs that are known to represent releases from Laboratory SWMUs or AOCs or other anthropogenic sources, whereas "COPC" is a more general term that also includes analytes identified in Section 6 that may or may not represent such releases.

The following discussion is divided into three sections. Section 7.1 describes spatial and temporal trends for contaminants in sediments and the fluvial processes controlling their distributions. Section 7.2 describes the hydrology of the watershed, including descriptions of surface water, alluvial groundwater, pore water, intermediate-perched groundwater and regional groundwater, and summarizes spatial and temporal trends for contaminants in these media. Together, the data presented in Sections 7.1 and 7.2 are used to identify contaminant sources and to understand contaminant transport away from the source areas. Section 7.3 presents a summary of the physical system conceptual model based on the combined contaminant and pathways data. Key aspects of the physical system conceptual model are shown in Figure 7.0-1. Supporting information about trends in hydrologic conditions and contaminant distributions that support the conceptual model is presented in Appendixes B, D, F, G, H, I, J, K, L, M, N, O and P.

In the following discussion, metric units followed by English units in parentheses are generally employed. However, some data such as transducer data for alluvial wells, precipitation data collected at TA-06, and streamflow gage data were all collected and reported in English units (feet, inches, and cubic feet per second, respectively). Because of the voluminous nature of these data, the original units are maintained in some graphs and tables.

7.1 Contaminants in Sediments

This section discusses general aspects of contaminants associated with sediment in the Mortandad watershed, including how the distribution and concentration of contaminants are affected by fluvial processes acting over decadal time periods after releases. Subsequent sections discuss details of the distribution and concentration of specific COPCs in sediment deposits in the watershed that are important for evaluating potential human health or ecological risk or the downcanyon transport of contaminants in floods. In this section, the term "contaminant" is used to refer to COPCs that are known to represent releases from Laboratory SWMUs or AOCs or other anthropogenic sources, whereas "COPC" is a more general term that also includes analytes identified in Section 6 that may or may not represent such releases. For example, some COPCs identified by comparison with BVs or detection limits may represent naturally elevated concentrations or false positives from analytical laboratories, as discussed below.

Most contaminants in sediment in the Mortandad watershed that were derived from Laboratory sources were originally released in wastewater from outfalls (Purtymun 1967, 11785; Purtymun 1971, 4795; Hakonson and Bostick 1976, 29678; Nyhan et al. 1982, 7164; LANL 1997, 56835). Because streambeds

on the Pajarito Plateau are usually dry, effluent that did not infiltrate into soils between the outfalls and the channel generally infiltrated into the streambeds. The downcanyon extent of effluent flow varied with release volume and prior moisture conditions along the channel. Nyhan et al. (1978, 5726) reported that in the early 1970s, when the discharge volume was relatively high (Figure 2.1-1), effluent extended for 1.5 km (1 mi) or less downcanyon from the TA-50 RLWTF outfall, indicating that infiltration of effluent in Mortandad Canyon during this period generally occurred upcanyon from reach M-3W. Observations from the early to mid-1960s indicate that effluent sometimes reached M-3W when TA-48 and TA-50 were concurrently discharging wastewater (Purtymun 1967, 11785, p. 36). Discharge volume has been progressively decreasing since the early 1980s (Figure 2.1-1), and infiltration of effluent at present occurs over a shorter stretch of channel.

Once in the streambed, dissolved contaminants commonly adsorb to sediment particles or organic matter because of the geochemical behavior of most radionuclides, metals, and organic chemicals that are of concern in this investigation (Watters et al. 1983, 11888; Salomons and Forstner 1984, 82304; Lopes and Dionne 1998, 82309). Exceptions include perchlorate and tritium which are highly soluble, nonsorbing analytes that remain dissolved in water; as discussed in more detail in Section 7.2. Many contaminants preferentially bind to clay minerals or organic particles, but they will also bind to other mineral particles. Contaminants will preferentially bind to smaller particles because of their larger ratio of surface area to mass and greater electrostatic attractions, and Nyhan et al. (1976, 11747) have documented a general inverse relation between contaminant concentration and particle size of streambed sediment on the Pajarito Plateau. Preferential adsorption to finer particles and organic matter also occurs when wastewater infiltrates into soils on hillslopes. Because of the general inverse correlation of contaminant concentrations with sediment particle size, concentrations can be an order of magnitude higher in the finest-grained sediment deposits, which contain up to 80% or more silt and clay than in coarse-grained sediment deposits that contain < 5% silt and clay (Reneau et al. 2004, 93174; LANL 2004, 87390).

Once adsorbed to sediment particles in the streambed, contaminants can subsequently be redistributed by floods that scour the streambed and mobilize the bed sediment. Contaminants in the streambed that originated as solid particles will behave similarly to those originally released as dissolved components in wastewater. Contaminants associated with coarse-size fractions (coarse sand and coarser; >0.5 mm [0.02 in.]) are generally transported as bed load along the streambed, whereas contaminants associated with fine-size fractions (fine sand and finer; <0.25 mm [0.01 in.]) are generally transported in suspension (Malmon 2002, 76038, pp. 108–114; Malmon et al. 2004, 93018). Contaminants associated with medium sand (0.25–0.5 mm [0.01–0.02 in.]) can be either transported as bed load or as suspended load. The coarse sediment fractions typically travel shorter distances during a flood than fine fractions because of their interactions with other sediment particles on the streambed, and they are usually redeposited within the channel during waning stages of a flood. In areas where the channel is aggrading (raising its elevation through sediment deposition) and where there are no stream banks or where banks are low, coarse sediment can be deposited over adjacent floodplains. In floods that overtop stream banks or where there are no stream banks, some of the fine particles and associated contaminants carried in suspension are also deposited on adjacent abandoned channels or floodplains as flow depth, and velocity decreases relative to the main channel. In large flood events, contaminants can be distributed across the entire width of floodplains in canyon bottoms. In reaches where transmission losses into the streambed exceed discharge, all sediment is deposited. Additional fine particles are deposited on or infiltrate into the streambed during waning stages of flow to be potentially scoured and resuspended in subsequent events.

During floods, sediment from a variety of sources is mixed, changing contaminant concentrations longitudinally along a channel. Where runoff from a contaminant source area enters a stream draining noncontaminated or less-contaminated areas, contaminant concentrations in sediment carried by a flood typically decrease relative to the source area while they increase relative to areas upstream from the

contaminant source. Downcanyon, where runoff from tributaries draining noncontaminated or less-contaminated areas joins a stream in flood, concentrations may be further reduced. Some of the sediment transported in floods is eroded from the bed and banks of the channel, and this erosion can also change contaminant concentrations in a flood. As a flood from noncontaminated areas erodes contaminated sediment downcanyon from source areas, contaminant concentrations in transported sediment increase. Similarly, when a flood draining contaminated areas erodes noncontaminated or less-contaminated material along the channel, concentrations in transported sediment decrease. The net result is a general downcanyon decrease in contaminant concentrations in sediment with distance from a contaminant source area (e.g., Marcus 1987, 82301; Graf 1996, 55537; Reneau et al. 2004, 93174) and an increase in contaminant concentrations along main channels where significant amounts of contaminants are provided from tributaries (LANL 2004, 87390).

Contaminant concentrations in sediment carried in floods also change over time in relation to the history of contaminant releases. Concentrations are generally highest during the period of peak contaminant releases and decrease over time as a result of the mixing processes discussed above. Such decreases over time have been documented in the Los Alamos and Pueblo Canyon system (Malmon 2002, 76038, pp. 315–322; LANL 2004, 87390, pp. 7–8; Reneau et al. 2004, 93174, pp. 1216–1217), as well as in other regions (Lewin et al. 1977, 82306, p. 357; Rowan et al., 1995, 82303, p. 61). Removing or stabilizing contaminants in source areas can help accelerate these natural decreases in contaminant concentrations over time.

Multiple floods occurring over decadal time periods result in sediment deposits in each reach that have a range in age and particle size distribution and hence in contaminant concentration. Schematic cross sections illustrating the distribution of coarse and fine sediment in reaches in the Mortandad watershed are shown in Figures 7.1-1, 7.1-2, and 7.1-3. The term “coarse facies” is used to refer to sediment with median particle size in the less than 2-mm (0.08-in.) fraction of medium to very coarse sand, and these deposits commonly have a high gravel content. The term “fine facies” is used to refer to sediment with median particle size of silt to medium sand. The active channel (c1 geomorphic unit) is typically dominated by relatively young coarse facies sediment deposits. In some parts of the Mortandad watershed, cattail wetlands occur along the active channel (c1ct unit; e.g., reach E-1W in Figure 7.1-2), and fine facies sediment is commonly deposited in these areas where floodwaters spread and energy drops. Abandoned channels (c2 and c3 units), which are areas occupied by the channel sometime after 1942 but subsequently abandoned following channel migration and/or channel incision, typically include fine facies sediment overlying older coarse facies sediment. Abandoned channels can also include coarse deposits as the uppermost, youngest layer (e.g., reach M-4C in Figure 7.1-3). Post-1942 floodplains (f1 unit) typically include thinner layers of post-1942 fine facies sediment that bury pre-1943 soils. (See Section B-1 of Appendix B for additional discussion of sediment facies and geomorphic units.)

As shown in Figures 7.1-1 and 7.1-3, the layers with the highest contaminant concentration in a reach are typically at depth, buried by younger sediment layers with lower concentrations, although they can also occur at the surface (e.g., cesium-137 in reach M-3E, Figure 7.1-2). The highest concentrations can also occur in very small sediment deposits in narrow canyons close to the sources, including the watershed maximums for americium-241, cesium-137, and strontium-90 in reach E-1E and chromium in reach E-1FW (Figure 7.1-1). These figures also show how the relation of sediment layers to trees provides one means of estimating the thickness and age of different sediment layers (tree age determined from tree-ring dating [dendrochronology]; see Section B-1 (in Appendix B) for more discussion of field investigation methods). Plates 2 through 5 show the distribution of geomorphic units in the investigation reaches.

Volumes of contaminated post-1942 sediment vary longitudinally along the canyons, resulting in part from variations in channel gradient and the width of post-1942 geomorphic units, as shown in Figure 7.1-4. Mortandad Canyon contains relatively large volumes of post-1942 sediment associated with wide areas of the canyon bottom near the Ten Site Canyon confluence. Width and volume of post-1942 sediment deposits in Mortandad Canyon increase beginning in reach M-3W, where the channel gradient decreases and the canyon bottom widens. Maximum volume is in reaches M-3E and M-4C, and the maximum average width of about 60 m (200 ft) is in M-4C. Other areas of locally high volume and width and lower gradient, relative to nearby reaches, include reaches E-1W, PCYN, TS-1C, and TS-3. In contrast, width and volume are generally lowest in relatively steep reaches, such as E-1FW, E-1E, and TS-2E.

Parts of Mortandad Canyon include discontinuous channels, features that are common in many arid and semiarid areas (Bull 1997, 93908) and that enhance the spreading and infiltration of floodwaters and the deposition of sediment and associated contaminants. Where channels end and runoff becomes unconfined, floodwaters can spread over large areas, such as M-4C and the western part of M-5W (Figure 3.2-1 and Plate 4). Runoff from these areas typically feed into headcuts, below which flow is again generally confined within narrow channels. Examples of the beginning of channels at headcuts occur in reaches M-4E and M-5W (Plate 4).

Most of the contaminants in sediments in Mortandad watershed occur in areas of post-1942 sediment deposition outside the active stream channels, as also seen in the Los Alamos and Pueblo watershed (LANL 2004, 87390; Reneau et al. 2004, 93174) and in Cañon de Valle (LANL 2003, 77965; Reid et al. 2005, 91247). At present, these deposits probably constitute the primary source for contaminants carried by floods, as observed in other regions (e.g., Rowan et al. 1995, 82303, pp. 63–64), with active channels and erosion from hillslopes constituting lesser sources. The concentration and inventory (amount) of contaminants in deposits outside the active channel vary longitudinally within the canyons. Concentrations are typically highest in fine sediment deposits near the sources that date to the period of contaminant releases and decrease in younger deposits, in coarser deposits, and downcanyon. Contaminant inventories display more irregular patterns than contaminant concentrations and are related to longitudinal variations in the volume, grain size, and age of sediment deposits within a canyon. Subsequent sections provide examples of the variations in contaminant concentration and inventory in sediment deposits within the Mortandad watershed.

Variations in background concentrations of some analytes in sediment can complicate the identification and evaluation of contaminants related to Laboratory releases. For example, background concentrations of fallout radionuclides in sediments have been shown to vary between regional rivers and reservoirs (McLin and Lyons 2002, 82305) and between these settings and canyons on the Pajarito Plateau (Ryti et al. 1998, 59730; McDonald et al. 2003, 76084). Background concentrations of some inorganic chemicals in sediments have also been shown to vary between different areas on the Pajarito Plateau as a result of local variations in soils or bedrock (Drakos et al. 2000, 68739). Because soils on the Pajarito Plateau have higher concentrations of many inorganic chemicals than sediments (Ryti et al. 1998, 59730), deposition of sediment derived from locally eroded soils provides a possible source for elevated concentrations of inorganic chemicals in sediments.

Mineralogic variations within naturally occurring sediment can also contribute to background variations, for example, the higher concentrations of many metals in black magnetite-rich sands on the Pajarito Plateau, such as iron, manganese, nickel, thallium, vanadium, and zinc (Reneau et al. 1998, 62050, pp. 12–14). Additional variations in background concentrations are the result of incorporation of ash transported from the Cerro Grande burn area, since ash contains higher concentrations of fallout radionuclides and many inorganic chemicals than pre-fire sediment (Katzman et al. 2001, 72660; Gallaher et al. 2002, 82265; Kraig et al. 2002, 85536; Johansen et al. 2003, 82312; LANL 2004, 87390).

Finally, concentrations of various inorganic and organic chemicals in sediment may be elevated near urbanized or industrial areas as a result of runoff from roads and other developed areas (Edwards 1983, 82302; Lopes and Dionne 1998, 82309; Walker et al. 1999, 82308; Breault and Granato 2000, 82310; van Metre et al. 2000, 82262), further complicating the identification and evaluation of contaminants related to Laboratory releases. The topics of variations in background concentration and contributions from developed areas as they relate to key contaminants in the Mortandad Canyon system are discussed in subsequent sections.

7.1.1 Radionuclides in Sediments

Nine radionuclides detected in sediments in the Mortandad watershed have maximum results greater than residential SALs and are more important for assessing potential human health risk: americium-241, cesium-137, cobalt-60**,** plutonium-238, plutonium-239,240, strontium-90, thorium-228, thorium-230, and thorium-232. This section focuses on spatial and temporal variations in radionuclides in the Mortandad watershed, and supporting information is included in Appendix D.

7.1.1.1 Sources and Spatial Variations in Radionuclide Concentrations

Radionuclides in sediments in the Mortandad watershed have several sources, as indicated by their spatial distribution, and concentrations typically decline downcanyon from the source areas. Subsequent discussions focus on the nine radionuclides that are most important for evaluating potential human health risk, based on comparison to residential SALs in Section 6.2.2: americium-241, cesium-137, cobalt-60**,** plutonium-238, plutonium-239,240, strontium-90, thorium-228, thorium-230, and thorium-232. Figure D-1.1.1 in Appendix D includes additional plots that show all sample results for radionuclide COPCs plotted against distance from the Rio Grande. Figure D-1.1.1 plots help to identify sources, although these data are biased high because fine-grained sediment layers from the most contaminated geomorphic units in a reach were preferentially sampled. In addition, these plots include some relatively high values from earlier sampling events that could not be replicated in later events.

Figures 7.1-5 to 7.1-10 show the estimated average concentrations of radionuclides whose concentrations and spatial trends indicate clear sources at Laboratory SWMUs or AOCs and whose maximum concentrations exceed residential SALs: americium-241, cesium-137, cobalt-60**,** plutonium-238, plutonium-239,240, and strontium-90. These are volume-weighted averages in post-1942 fine facies sediment in investigation reaches, where average radionuclide concentrations in a geomorphic unit in a reach are weighted by the volume of fine facies sediment in that unit, removing most of the bias introduced during sample collection. (Sample collection is biased toward geomorphic units and sediment facies with relatively high contaminant concentrations, as discussed in Section B-1 of Appendix B, and straight averages of all sample results from a reach are overestimates of true averages.) Averages for fine facies sediment are shown because average concentrations in this type of sediment are, with a few exceptions, higher than in coarse facies sediment, and fine facies deposits are therefore more important for evaluating risk. Average concentrations for both fine and coarse facies sediment in each reach are presented in Tables D-1.5-1 to D-1.5-6 (Appendix D). In Figure 7.1-10, the sediment BV for strontium-90 is shown for comparison; BVs are too low for the other radionuclides to show at the scales used in the figures.

The most important sources for radionuclide COPCs in the Mortandad watershed are the TA-50 RLWTF outfall into reach E-1E, the former TA-35 WWTP outfall into Pratt Canyon (reach PCYN), and the accidental releases in 1974 from TA-50 into the head of Ten Site Canyon (reach TS-1W), as shown in Figures 7.1-5 to 7.1-10. Average concentrations of americium-241, cesium-137, cobalt-60**,** and plutonium-239,240 are highest in reach E-1E in Effluent Canyon, and plutonium-238 and strontium-90 are

also present there above background concentrations. Average concentrations of plutonium-238 are highest in Ten Site Canyon between TA-50 and Pratt Canyon; americium-241, cesium-137, cobalt-60, plutonium-239,240, and strontium-90 have also been identified there as COPCs. Average concentrations of strontium-90 are highest in Pratt Canyon; and americium-241, cesium-137, cobalt-60, plutonium-238, and plutonium-239,240 have also been identified there as COPCs. Some of these radionuclide COPCs have been detected above BVs in other areas that suggest the possibility of additional sources, but concentrations are low, and no significant increase in average concentrations is indicated in Figures 7.1-5 to 7.1-10. If releases of radionuclides occurred from other SWMUs or AOCs, they were apparently small.

The pattern of downcanyon decline in radionuclide concentrations is notably different between the different sources, as shown in Figures 7.1-5 to 7.1-10. Downcanyon from the RLWTF outfall into Effluent Canyon, radionuclides generally show decreasing trends for about 3–4 km (1.9–2.5 mi), east of which their average concentrations are similar to background levels. In Ten Site Canyon, the highest concentrations of plutonium-238 are found within 1 km (0.6 mi) of the accidental releases from TA-50, and concentrations are much lower downcanyon—less than in Mortandad Canyon, which is an equal distance downcanyon from the RLWTF (Figure 7.1-8). Similarly, although the average concentration of strontium-90 is much higher in Pratt Canyon than in Effluent Canyon, concentrations are relatively low farther downcanyon in Ten Site Canyon compared with Mortandad Canyon above the Ten Site Canyon confluence (Figure 7.1-10). The occurrence of relatively low-gradient areas near the contaminant sources in Pratt and Ten Site Canyons, where sediment is preferentially deposited (Figure 7.1-4), contributes to the differences seen between canyons. The relatively small drainage areas of Pratt and upper Ten Site Canyons, compared with Mortandad Canyon below the Effluent Canyon confluence, also lead to smaller-magnitude floods and lower transport rates of sediment and associated contaminants from Pratt and upper Ten Site Canyons.

Several deviations from the general downcanyon decline in average radionuclide concentrations are seen in Figures 7.1-5 to 7.1-10 that reflect some of the complexity in the present distribution of contaminants. This complexity probably results at least in part from the combined effects of temporal variations in contaminant releases and spatial and temporal variations in downcanyon sediment erosion and deposition during floods in the subsequent decades, as documented previously in the Los Alamos and Pueblo watershed (LANL 2004, 87390; Reneau et al. 2004, 93174). For example, the higher average concentrations of cesium-137 and other radionuclides in reach M-3E than the concentrations that are immediately upcanyon in M-3W probably records preferential deposition of sediment in M-3E during the period of peak cesium-137 releases from the RLWTF and the general stability of these sediment deposits since that time (as discussed later). In contrast, analytical data from reach M-3W indicate that most of the sediment is younger, postdating the period of peak releases, recording either nondeposition or subsequent erosion of deposits from that time period. The higher average concentrations of cesium-137 and plutonium-238 in M-2E relative to M-2W may similarly record preferential deposition in M-2E during the period of peak releases of these radionuclides, in contrast to americium-241, cobalt-60, plutonium-239,240, and strontium-90, which have higher average concentrations in M-2W.

The general downcanyon decrease in average radionuclide concentrations discussed above applies only to historic sediment deposits that integrate the effects of changing discharge from the sources and downcanyon transport over decadal time frames. Samples collected from the active channel (c1 unit) and associated low surfaces (c1b unit) in 2004 from the TA-50 RLWTF outfall to near the confluence of Mortandad and Ten Site Canyons show a different pattern. This pattern indicates the primary source of radionuclides currently transported by floods is remobilization of sediment previously stored along the channel and in adjacent geomorphic units. Figure 7.1-11 shows that fine facies sediment adjacent to the channel in 2004 (median particle size of coarse silt to fine sand) had the lowest concentrations of cesium-137 in reach E-1E near the RLWTF outfall and that concentrations progressively increased

downcanyon. Cesium-137 concentrations in coarse facies sediment (median particle size of coarse to very coarse sand) were much lower than in the fine facies sediment but also showed relatively low concentrations near the outfall and higher concentrations downcanyon. Concentrations in fine facies sediment increased downcanyon in 2004 because of the erosion of sediment deposits along the channel containing relatively high concentrations of cesium-137. The relatively low concentrations in E-1E, close to the outfall in the reach with the highest concentrations of cesium-137 in older sediment deposits, suggest that most of the sediment in the active channel in this reach is derived from upcanyon of the RLWTF outfall, with relatively small contributions from bank erosion in E-1E. In contrast to the fine facies samples, cesium-137 concentrations in coarse facies samples are similar from M-2W to M-3E, except for a somewhat higher result in M-3W (Figure 7.1-11), suggesting that neither net enhancement nor dilution of cesium-137 is occurring over this 2-km stretch of canyon in coarse sediment associated with mixing of sediment from different sources.

Data from environmental surveillance sampling stations (e.g., ESP 2005, 92222), representing sediment collected from the stream channel, show the same lack of systematic variations in cesium-137 concentration between Effluent Canyon and the Ten Site Canyon confluence (reaches M-2W to M-3E) as seen in coarse facies samples from 2004. Figure 7.1-12 shows average concentrations of cesium-137 in samples collected over the 10-yr period from 1996 to 2005 at surveillance stations in Mortandad Canyon. Concentrations are relatively high and similar at the stations below Effluent Canyon (gaging station E200, reach M-2W), at well MCO-5 (reach M-3W), and above the sediment traps (gaging station E202, confluence of Mortandad and Ten Site Canyons). Concentrations decrease downcanyon from there to well MCO-9.5, west of reach M-5W, and are at background levels farther downcanyon. Cesium-137 concentrations are also at background levels in Mortandad Canyon above Effluent Canyon (Figure 7.1-12).

For several radionuclides that have maximum results above residential SALs, available data do not indicate clear sources at Laboratory SWMUs or AOCs and/or releases that were large enough to noticeably affect average concentrations in a reach. Specifically, thorium-228, thorium-230, and thorium-232 all have maximum values above sediment BVs, but average concentrations calculated for both fine and coarse facies sediment are generally less than background averages, as shown in Table D-1.5-7. Thorium-228 only had one result above the BV, from reach TS-1C in 2004 (sample CAMO-04-53373), and resampling of this sediment layer in 2005 yielded a result below the BV (sample CAMO-05-63743). Thorium-230 had only three results above the BV: two from TS-1C (samples CAMO-04-53373 and CAMO-04-53376) and one from reach MCW-1 (sample CAMO-03-49826). The MCW-1 result was only 7% higher than the BV (2.44 vs. 2.28 pCi/g), and resampling of the TS-1C sample layers in 2005 yielded thorium-230 results below the BV (samples CAMO-05-63743 and CAMO-05-63744). Thorium-232 had three results above BVs: one from M-1C and two from TS-1C. The M-1C result was less than twice the BV (3.48 vs. 2.33 pCi/g), and the TS-1C results were not confirmed upon the resampling discussed for thorium-228 and thorium-230. In summary, available data for these thorium isotopes do not clearly indicate sources at SWMUs or AOCs, and if releases occurred, they were too small to elevate average concentrations in a reach above background averages.

7.1.1.2 Collocation of Radionuclides

The different radionuclide COPCs are generally collocated in sediment deposits in the different reaches in the Mortandad watershed, primarily occurring in post-1942 sediment deposits and preferentially occurring in fine rather than coarse facies sediment. However, the maximum concentrations of each radionuclide may not occur in the same sediment layers in each reach because the relative concentrations of radionuclides in effluent released from outfalls varied over time both as a result of changes in research activities at the Laboratory and changes in wastewater treatment methods. These variations are

discussed further in Section 7.1.1.3. Additional variations result from the mixing of sediment and associated contaminants from different sources and possibly from variable geochemical behavior between radionuclides.

The best correlations between radionuclides downcanyon from the TA-50 RLWTF outfall generally occur between americium-241 and plutonium-239,240 and between cesium-137 and strontium-90, suggesting similar histories of release and transport for these pairs of radionuclides. Good correlations can also exist between other pairs of radionuclides in a reach, although in the complete data set more variability is present that indicates the presence of multiple populations of samples. As examples, Figure 7.1-13 presents scatter plots that show relations between select pairs of radionuclides in M-2E and in the entire data set from the RLWTF outfall through M-4. Both data sets show good correlations between cesium-137 and strontium-90. Correlations are also generally good between americium-241 and plutonium-239,240, although a scattering of samples with high results for plutonium-239,240 deviate from the general trend. Good correlations exist between cesium-137 and plutonium-238 in M-2E, but in the entire data set, distinct populations can be seen that record differences in the ratios between these radionuclides, and the overall correlation is poor. For comparison, relations between plutonium-238 and plutonium-239,240 are poor in both data sets. As discussed in Sections 7.1.1.3 and D-1.6 (Appendix D), populations of samples with different radionuclide ratios are associated with changes in the RLWTF release history and reflect sediment deposits of different age.

Plutonium-238 has maximum concentrations in the Mortandad watershed in Ten Site Canyon upcanyon from Pratt Canyon, and plutonium-239,240 is also elevated in the same reaches. The maximum measured concentrations of both plutonium-238 and plutonium-239,240 in Ten Site Canyon occur in the same sample (CAMO-04-53381), a subsurface layer of fine facies sediment in reach TS-1E. Similar but slightly lower values of both isotopes occur in a subsurface layer of fine facies sediment in reach TS-1C (CAMO-04-53378). These data support simultaneous release and similar behavior of these plutonium isotopes in this part of Ten Site Canyon.

Radionuclide concentrations in Ten Site Canyon show less collocation downcanyon from Pratt Canyon, consistent with mixing of sediment from different sources and variable release histories. The highest concentration of strontium-90 in Ten Site Canyon was measured in a fine facies sediment layer in reach TS-2E, about 420 m (1380 ft) downcanyon from Pratt Canyon. The highest plutonium-239,240 concentration in this part of Ten Site Canyon was measured in a different layer in TS-2E, and the highest plutonium-238 concentration downcanyon from Pratt Canyon was measured in a fine-grained sediment layer in TS-2W.

7.1.1.3 Temporal Variations in Radionuclide Concentration

Data from Mortandad Canyon show that the concentrations of radionuclides in both fine- and coarse-grained sediment generally decreased over time following peak contaminant releases. Some examples of these data are presented below. Additional plots of environmental surveillance data for key radionuclides are presented in Section D-1.2 of Appendix D.

Figure 7.1-14 shows time series of cesium-137 concentrations measured at three environmental surveillance stations in Mortandad Canyon since 1977, supplemented by active channel samples from the reach investigations in 1998 to 2005 and from investigations by the Environmental Science Group in 1972 and 1973 (Nyhan et al. 1978, 5726; results from 0–7.5-cm depth). During this period, concentrations in reach M-2W were highest in the 1970s, decreasing to near present values by 1985. Concentrations in reach M-3W were highest in the early 1970s, decreasing more gradually to near present values by 1995.

Concentrations in reach M-4W were highest from the late 1970s to the early 1980s, also decreasing to near present values by 1995. Cesium-137 concentrations have been relatively constant in the active channel at all three sites since about 1995. These data indicate that the effects of the discharge of cesium-137 from the RLWTF were most pronounced close to the source, but concentrations also decreased most rapidly there. Reductions in cesium-137 concentration over time in channel sediments were slower farther downcanyon, although concentrations have been relatively stable for 10 yr in these areas.

Data collected by the Environmental Science Group in 1972 and 1973 (Nyhan et al. 1978, 5726) document the high variability and high concentrations that existed in radionuclides in the active stream channel close to the RLWTF outfall during the early period of releases. Analyses from the Effluent Canyon channel include the highest reported cesium-137 concentrations from the Mortandad watershed, greater than 3000 pCi/g. Figure 7.1-15 plots the results of this sampling (0–7.5-cm depth) versus distance from the outfall and shows that cesium-137 concentrations varied by a factor of 6 in reach E-1E in a single year and also varied between years. In samples from two locations in reach M-2W, cesium-137 concentrations varied by a factor of 2 between 1972 and 1973. Farther downcanyon, in reaches M-2E and M-3W, cesium-137 concentrations were less variable between years. These data support the conceptual model first proposed by Purtymun et al. (1966, 11848; see also Purtymun 1971, 4795; Nyhan et al. 1978, 5726) that during periods of radioactive effluent release, radionuclides first build up in the stream channel alluvium where the effluent infiltrates into the bed. These radionuclides are subsequently remobilized by higher magnitude stormwater runoff events that scour the bed, being transported with sediment particles farther downstream. The high spatial and temporal variability seen in reaches E-1E and M-2W in Figure 7.1-15 is interpreted to correspond to the area where most of the effluent was infiltrating into the streambed and being periodically scoured, and the lower variability downcanyon is interpreted to largely record the effects of sediment mixing during subsequent downcanyon transport, although some direct contact with effluent was reported at the M-2E site (Nyhan et al. 1982, 7164, p. 532).

Figure 7.1-16 shows reconstructions of the concentrations of five key radionuclides in fine facies sediment in reaches M-3, M-4W, and M-4E near the confluence of Mortandad and Ten Site Canyons between 1960 and 2005. These reconstructions use data from sediment samples collected in this investigation and provide trends consistent with discharge records from the RLWTF. The basis for age estimates for individual sediment layers is discussed in Section D-1.6 in Appendix D. Plots for cesium-137 and strontium-90 have been adjusted for radioactive decay to show both estimated average concentrations at the time of deposition and average concentrations in 2006 when this report was written.

Americium-241 and plutonium-239/240 show very similar trends, with very low concentrations before 1975, well-defined maximum concentrations at ca. 1979–1983, and concentrations near current levels after about 1990 (Figure 7.1-16). Discharge records similarly show maximum releases of these radionuclides in 1981–1983 (LANL 1997, 56835, pp. 2-20, 2-21), which indicates rapid transport over the 3 km from the outfall to the confluence of Mortandad and Ten Site Canyons. Plutonium-238 is present at much lower concentrations, with an earlier peak at ca. 1975–1977 that is consistent with discharge records indicating peak releases in 1974–1975 (LANL 1997, 56835, pp. 2-20, 2-21). Plutonium-238 also has a secondary peak of slightly lower magnitude at ca. 1979–1983. Cesium-137 shows more variability in concentrations, with similar-magnitude peaks in the late 1960s and at ca. 1975–1977; no cesium-137 discharge data from the RLWTF are available from this period for comparison. Strontium-90 shows the highest concentrations in the late 1960s, which is consistent with discharge records that indicate the peak releases in 1964–1965 (LANL 1997, 56835, pp. 2-20, 2-21). Figure 7.1-16 shows that by 2006, concentrations of cesium-137 and strontium-90 in sediment deposits from the late 1960s have been

reduced by about 60% due to radioactive decay. Both cesium-137 and strontium-90 show gradual decreases in concentration since about 1987, which may also be largely caused by radioactive decay.

7.1.1.4 Relations between Particle Size and Radionuclide Concentration

The particle size distribution of sediment deposits can have a strong influence on radionuclide concentrations because of the preferential tendency for radionuclides to adsorb onto small particles, although these relations can be obscured because of temporal variations in radionuclide release history and other factors (Reneau et al. 1998, 59160; Reneau et al. 2004, 93174; LANL 2004, 87390). General inverse relations between contaminant concentration and particle size within streambed sediment in Effluent and Mortandad Canyons were previously documented by Nyhan et al. (1976, 11747) for samples collected in the early 1970s. The data collected in this investigation provide additional insights into relations between particle size and radionuclide concentrations in the Mortandad watershed, as discussed below.

Figure 7.1-17 plots concentrations of select radionuclides in sediment samples from the Mortandad watershed against percent silt and clay content (percent in the <2-mm fraction of the sample). Cesium-137 is shown for plots in Effluent and Mortandad Canyons downcanyon from the TA-50 RLWTF outfall (reaches E-1E, M-2W, M-2E, M-3, and M-4), and strontium-90 is shown for Ten Site Canyon downcanyon from Pratt Canyon (reach TS-2). With one exception, radionuclide concentrations in these reaches are highest in fine facies sediment deposits with relatively high silt and clay content. The exception is reach M-2W, where cesium-137 concentrations are highest in coarse facies sediment collected from the c3 and f1g units, although within these samples there is a good correlation between cesium-137 and silt and clay content (Figure 7.1-17). The coarse facies deposits in c3 and f1g are interpreted to represent the active streambed during the period of highest cesium-137 discharges, with the high concentrations resulting from the direct interaction of effluent with streambed sediment. Lower concentrations in coarse facies sediment in other reaches suggest that sampled deposits did not have direct contact with effluent during this period.

The highest radionuclide concentrations in other reaches generally occur in deposits with relatively high silt and clay contents, although there is generally much scatter between radionuclide concentrations and silt and clay content in each reach (Figure 7.1-17). This variability probably results in part from the large temporal variations in radionuclide concentrations discussed in Section 7.1.1.3, combined with the mixing of sediment from different sources. Subsets of the data in a reach can display much more systematic relations, such as the good correlations between cesium-137 and silt and clay content in sediment from ca. 1990 to 2005 in M-3 and M-4 (Figure 7.1-17). The effect of deposit age can be seen in M-4, where the samples with the highest cesium-137 concentration (148–276 pCi/g) were from silt and clay-rich sediment deposited ca. 1974–1978. The relatively high cesium-137 concentrations in fine facies sediment in c3 and f1 units in E-1E and in c3 and f1g units in M-2E (Figure 7.1-17) probably also record sediment deposited during periods of high cesium-137 releases.

7.1.1.5 Radionuclide Inventory

Data collected in this investigation define the general geographic variations in the amount, or inventory, of radionuclides contained in sediment deposits in different parts of the Mortandad watershed. Table 7.1-1 summarizes the geographic distribution of americium-241, cesium-137, cobalt-60, plutonium-238, plutonium-239,240, and strontium-90 in sediment deposits in the watershed, which updates and expands on estimates of cesium-137 inventory in a previous report (Reneau et al. 2003, 77103). Supporting data for Table 7.1-1 are presented in Section D-1 of Appendix D. No inventories are estimated for reaches where these analytes are not COPCs (which would largely or entirely represent inventories associated

with background concentrations). Inventory estimates are also not shown for Mortandad Canyon above Effluent Canyon, Mortandad Canyon east of M-5E, or the unnamed tributary canyon that heads in TA-05 because these areas include less than 0.2% of the estimated inventory for each radionuclide. The inventory estimates in Table 7.1-1 are not adjusted for sediment removed during maintenance of the sediment traps in 2000 (WGII 2000, 70735), although the inventory removed is expected to be minor because of the low concentrations present in the traps and in adjacent fill piles. Estimated inventories are also not adjusted for radioactive decay, which would be more important than the maintenance activities for cesium-137, cobalt-60, and strontium-90 because of their relatively short half-lives (30.1, 5.27, and 28.8 years, respectively; Parrington et al. 1996, 58682). For example, radioactive decay would reduce the concentration of cesium-137 and strontium-90 in a layer sampled in 1998, the first year of this investigation, by about 17% by 2006, the date of this report. Estimates of the amount redistributed by floods since characterization was done are not included, although these will have resulted in some reduction in inventory in upcanyon reaches and increases in downcanyon reaches since this investigation began. Estimates of additions of radionuclides from the RLWTF outfall or from erosion from SWMUs or AOCs are also not included, although these are expected to be minor relative to the total watershed inventory in the canyon bottoms.

Table 7.1-1 shows that reach M-3E in Mortandad Canyon upcanyon from the Ten Site Canyon confluence contains the largest amounts of key radionuclides in the watershed, an estimated 50% to 55% of the americium-241, cesium-137, cobalt-60, and plutonium-239,240. Mortandad Canyon between Effluent Canyon and M-3E contains the second largest amounts of these radionuclides, and reach M-4 contains the third largest amounts. Effluent Canyon contains relatively small amounts of all radionuclides because of the small sediment volumes in the steep and narrow canyon below the TA-50 RLWTF outfall. Ten Site Canyon contains an estimated 33% of the plutonium-238, indicating the importance of the accidental releases in 1974 from TA-50 into the head of the canyon but contains relatively low percentages of the remaining radionuclides. Pratt Canyon is notable for strontium-90, containing an estimated 39% of the watershed inventory, although geomorphically Pratt Canyon is not as well characterized as other reaches and has more uncertainty in the strontium-90 inventory. Because sampling in Pratt Canyon was biased to layers with relatively high field radiation measurements, the total strontium-90 inventory is probably overestimated.

Figure 7.1-18 shows the inventory of cesium-137 in Effluent and Mortandad Canyons plotted against distance from the Rio Grande. The cesium-137 inventory in this figure is plotted both as a normalized inventory in each reach per kilometer of channel ([a] units of mCi/km) and as cumulative amounts from the TA-50 RLWTF outfall to reach M-6 adjacent to SR 4 ([b] units of mCi). The cumulative plot extrapolates between sampled reaches. Figure 7.1-18 shows the estimated inventories in coarse and fine facies sediment deposits as well as the total inventory. Cesium-137 was chosen for these plots because it is the most important radionuclide in the watershed from the perspective of potential human health risk, based on a comparison to residential SALs, and because it illustrates the distribution of a key radionuclide downcanyon from the major source area.

Figure 7.1-18 shows that the radionuclide inventory varies considerably between reaches and that essentially the entire inventory is confined to approximately 4 km (2.5 mi) of canyon between the TA-50 RLWTF outfall and reach M-5W. Most of the inventory is contained within fine facies sediment deposits, and an estimated 79% of the cesium-137 in Effluent and Mortandad Canyons is in deposits of fine facies sediment. The most significant area for cesium-137 inventory in Mortandad Canyon is in reach M-3E, 2.1 to 2.7 km (1.3 to 1.7 mi) downcanyon from the outfall. The inventory is relatively high in this reach because of the deposition of large amounts of sediment where the stream gradient decreases and the canyon bottom widens (Figure 7.1-4). Data from a gross-gamma radiation walkover survey clearly show

the general pattern of cesium-137 deposition in M-3E where floodwaters spread over the canyon bottom (Figure 7.1-19).

7.1.1.6 Flood Attenuation and Downcanyon Extent of Radionuclide Contamination

Gaging station records of stream discharge (e.g., Shaull et al. 2005, 92225; Shaull et al. 2006, 93735), observations made during this investigation, and historical records presented in the work plan (LANL 1997, 56835) indicate that floods generated from upper Mortandad Canyon, Effluent Canyon, and Ten Site Canyon significantly attenuate as they move downcanyon, recording transmission losses into the alluvium. For example, from 1997 to 2004, 16 stormwater events occurred with estimated peak discharges exceeding 10 ft^3/s) recorded at gaging station E200 in Mortandad Canyon, 30 m (100 ft) below the Effluent Canyon confluence, and no events of this size recorded at gaging station E202 2.5 km (1.5 mi) downcanyon, near the confluence of Mortandad and Ten Site Canyons (Shaull et al. 2005, 92225, pp. 49, 125). Field observations indicate that stormwater that reaches the west end of reach M-3E near test well TW-8 generally infiltrates into the alluvium completely before arriving at the Mortandad-Ten Site Canyon confluence 0.6 km (0.4 mi.) downcanyon. These observations are consistent with the occurrence of over 50% of the cesium-137 inventory in M-3E (Section 7.1.1.4), recording deposition of most of the historic sediment load as stormwater infiltrates into the alluvium in this reach. In this area, both the canyon bottom and the active channel widen substantially and the channel gradient decreases (Figure 7.1-4 and Table B-1.0-1 [in Appendix B]), which slows stormwater and enhances its ability to infiltrate.

The distribution of cesium-137 and other radionuclides indicates that stormwater that passed the Mortandad-Ten Site Canyon confluence also generally infiltrated into the alluvium within reach M-4, even before excavation of the current sediment traps in 1986 or the original smaller traps in 1976. The canyon bottom does not have a defined channel in M-4C, east of the sediment traps, and stormwater that reached this area historically spread over an area averaging about 60 m (200 ft) in width, further enhancing infiltration and sediment deposition. The estimated cesium-137 inventory in the first 210 m (690 ft) past the sediment traps, in M-4C, is 4 times as high as the inventory in the next 230 m (755 ft), in M-4E (Table D-1.4-2), documenting this deposition of sediment and associated contaminants. The construction of the sediment traps therefore helped enhance a process of infiltration and sediment deposition that was occurring previously.

Since construction of the current sediment traps in 1986, there are only five known occurrences of overflow: June 7, 1987; July 24, 1991; August 6, 1991; August 24, 2005; and August 25, 2006. The downcanyon extent of the 1987 flood is not known, but in 1997 it was reported to be the “largest runoff event in Mortandad Canyon since hydrologic studies began in the canyon in 1960” (LANL 1997, 56835, p. 3-77). In 1991 flow was reported to have extended 200 m (650 ft) past sediment trap #3 (EPG 1993, 23249; LANL 1997, 56835, pp. 3-80, 3-83), and in 2005 flow extended 85 m (280 ft) past the overflow point of sediment trap #3 before infiltrating into the alluvium (Plate 4). The largest flood since initial releases from the TA-50 RLWTF occurred on August 25, 2006, with flow extending to reach M-5E within 65 m (215 ft) of the Laboratory boundary.

Records of earlier flows are sparse, and only one known event has had possible flow to the Laboratory boundary in reach M-5E, in August 1952, when a record 11.2 in. of precipitation was recorded in Los Alamos in 1 month, and flow in this event may have extended to SR 4 below reach M-6 (LANL 1997, 56835, pp. 3-16, 3-81). This was before initial releases from the TA-50 RLWTF in 1963 but after releases began from the TA-35 WWTP into Pratt Canyon in 1951. An additional large runoff event was noted in November 1978, with flow as far east as well MCO-9, between reaches M-4E and M--5W (Purtymun 1994, 52951, pp. 132–135; LANL 1997, 56835, p. 3-77).

Radionuclides display the clearest evidence of contamination in sediment deposits in the Mortandad watershed from Laboratory releases, possessing the highest concentrations relative to BVs or detection limits and the most systematic downcanyon trends. Therefore, radionuclide data provide insight into the downcanyon extent of Laboratory-derived contaminants that have been transported by floods. Five radionuclides have been detected above BVs in sediment downcanyon of reach M-4E (cesium-137, plutonium-238, plutonium-239,240, strontium-90, and uranium-235), and one additional radionuclide without a BV has been detected east of M-4E (cesium-134). None of these radionuclides were identified as COPCs in reach M-6 near SR 4, indicating the absence of recognizable transport of Laboratory-derived contaminants past SR 4.

The eastern identified extent of strontium-90 above the BV is in reach M-5W, although only one sample had a result above the BV (CAMO-04-53299, 1.68 pCi/g, vs. BV of 1.04 pCi/g). The other five radionuclides are COPCs in reach M-5E at the Laboratory boundary, although with generally low detection frequencies and low values above BVs. Cesium-137 was detected in only 1 out of 23 samples slightly above the BV (sample CAMO-00-0033, 0.93 pCi/g vs. BV of 0.9 pCi/g). Plutonium-238 was detected in 2 out of 23 samples above the BV, with a maximum of 0.09 pCi/g (sample CAMO-04-53326, vs. BV of 0.006 pCi/g). Plutonium-239,240 was detected in 8 out of 23 samples above the BV, with a maximum of 0.13 pCi/g (sample CAMO-04-53326, vs. BV of 0.068 pCi/g). Uranium-235 was detected in 1 out of 10 samples above the BV, with a maximum of 0.27 pCi/g (sample CAMO-04-53325, vs. BV of 0.2 pCi/g). Cesium-134, without a BV, was detected in 4 out of 18 samples, with a maximum of 0.1 pCi/g (sample CAMO-04-53325). In summary, the available analytical data indicate possible transport of several radionuclide COPCs as far as reach M-5E but not as far as M-6. The highest values relative to BVs are for plutonium-238 and plutonium-239,240, and the highest detection frequency above BVs is for plutonium-239,240. However, understanding the source of plutonium isotopes is complicated by the inference from regional soil data that plutonium may also be dispersed at levels above BVs by local Laboratory stack emissions and/or by fugitive dust from Laboratory sites (Fresquez et al. 1998, 76063), and the plutonium results in M-5E may or may not record past flood transport.

7.1.1.7 Future Fate and Transport of Radionuclides in Sediment

The concentrations and distribution of radionuclides present in sediment deposits in the Mortandad watershed will continue to change over time as a result of redistribution by floods and radioactive decay, as well as from any additional effluent discharges. Available data show progressive decreases in radionuclide concentration over time, driven largely by decreasing releases from the RLWTF, combined with the effects of mixing of sediment from different sources during transport and radioactive decay for radionuclides with relatively short half-lives such as cesium-137, cobalt-60, and strontium-90. Barring significant increases in the discharge of radionuclides, concentrations can be expected to generally continue declining over time, with a simultaneous downstream redistribution of inventory toward the confluence of Mortandad and Ten Site Canyons. Therefore, the present state of the watershed represents “worst-case” conditions from the perspective of potential future radionuclide contamination.

7.1.2 Inorganic Chemicals in Sediments

Three inorganic chemicals detected in sediments in the Mortandad watershed have maximum concentrations greater than residential SSLs and are most important for assessing potential human health risk: arsenic, chromium, and iron. Additional inorganic chemicals detected in sediment samples are important for assessing potential ecological risk (e.g., copper, cyanide, lead, mercury, perchlorate, thallium, vanadium, and zinc), for understanding relations between COPCs in water and sediment (e.g., lead, manganese, perchlorate, and selenium), or for understanding potential off-site transport onto San Ildefonso Pueblo land (e.g., copper cyanide, and selenium). The spatial distribution of these

inorganic chemicals (discussed below) indicates that they are derived from a variety of sources, including Laboratory SWMUs or AOCs, roads and other developed areas, and naturally occurring soils and bedrock. Once in the canyon bottoms, most of these inorganic chemicals adsorb to sediment particles and organic matter, and their subsequent fate is expected to be similar to that of radionuclides discussed in Section 7.1.1. However, inorganic chemicals derived from runoff from developed areas or from erosion of natural soils in the watershed differ from radionuclides in that these chemicals will not show the same decreases over time, and the concentrations of constituents derived from runoff from developed areas may actually increase over time.

This section focuses on spatial variations in inorganic chemicals in the Mortandad watershed. Supporting information is included in Appendix D. Table D-1.7-1 presents average concentrations in each reach for inorganic chemicals that are discussed in this section, substituting one-half of the detection limit for nondetected sample results. Averages presented here are weighted by the volume of sediment in each geomorphic unit in each reach, as discussed in Section D-1.3. Table D-1.7-1 presents the upper and lower bounds on these averages using either the detection limit or zero for nondetects, respectively, which indicate uncertainties in the average values. This table shows that on average, concentrations of these inorganic chemicals are generally lower in coarse facies sediment than in fine facies sediment, and Figure 7.1-20 and the discussions in the following sections focus on data from fine facies sediment. Figure 7.1-16 and Table D-1.7-1 also indicate that considerable uncertainty in the average concentration of some inorganic chemicals exists in some reaches because of elevated detection limits and/or detected concentrations close to detection limits, such as selenium and thallium.

The plots in Figure 7.1-20 include both the BV for each inorganic chemical, which is an estimate of the upper level of background concentrations, and the average value from the background sediment data set, where available (averages from McDonald et al. 2004, 76084, Table 10, p. 49–50). The background averages are included to be consistent with the presentation of averages from potentially contaminated samples. The spatial distribution of inorganic chemicals indicates that several TAs have been important Laboratory sources for these constituents in the Mortandad watershed, as discussed below.

Average concentrations of arsenic in fine facies sediment are greater than the sediment BV in two reaches, E-1FW and M-1E, both downgradient from TA-48 SWMUs or AOCs (Figure 7.1-20), indicating a source at this TA. Decreasing concentrations are present downcanyon from these reaches, and arsenic concentrations are similar to background averages east of M-2W in Mortandad Canyon. Average arsenic concentrations in M-1W and TS-2E are also above background averages but below the BV, indicating possible sources in TA-03 and from the TA-35 sand filter-bed outfall (AOC C-35-007).

Chromium data indicate a clear source at TA-48, with maximum concentrations in the Mortandad watershed in reach E-1FW, at the head of Effluent Canyon, and decreasing concentrations downcanyon. These data are consistent with known usage of potassium dichromate as a corrosion inhibitor in cooling towers at TA-48, as discussed in Section 7.2.2.1. Average chromium concentrations in fine facies sediment in E-1FW are roughly 100 times greater than in the next highest reach, E-1E, and average concentrations are the same as background averages by the Mortandad-Ten Site Canyon confluence (reach M-4W), 3.3 km (2.0 mi) downcanyon (Figure 7.1-20). Data from M-1C and M-1E, where average concentrations are greater than the BV, indicate one or more additional sources from TA-03 and possibly TA-48 into Mortandad Canyon. An additional minor source is suggested at the TA-35 sand filter-bed outfall by data from TS-2E where average concentrations of chromium are greater than the background average and close to the BV. Analyses of seven samples from E-1FW and E-1W indicate that the chromium in sediment is dominated by trivalent chromium (chromium[III]), with <0.4% hexavalent chromium (chromium[V1]). This contrasts with data from groundwater that indicate a dominance of

chromium(VI) in that media and is consistent with chemical reduction of chromium associated with the presence of organic carbon in sediments (Section 7.2.2.1).

Chromium is an important contaminant in the regional groundwater system beneath Mortandad Canyon (Section 7.2.2.1; LANL 2006, 91987), and the inventory of chromium present in sediment deposits in the Mortandad watershed as a result of Laboratory operations was estimated to allow comparison with the estimated amount released into the adjacent watershed of Sandia Canyon. The inventory estimates are presented in Table D-1.8-1 of Appendix D and indicate that about 75% of the anthropogenically added chromium in the watershed (subtracting background concentrations) is within Effluent Canyon, almost all above the TA-50 RLWTF outfall, and an additional 12% is within Mortandad Canyon downcanyon of the Effluent Canyon confluence. Most of the chromium associated with sediment has therefore been retained within sediment deposits near the source, with relatively small amounts transported farther downcanyon. The chromium inventory between the main source at TA-48 and SR 4 (reach M-6) is shown graphically in Figure 7-1-21. The inventory estimate indicates that an additional 11% of the watershed inventory is within Mortandad Canyon upcanyon from Effluent Canyon, and only about 1% is in Ten Site Canyon (Table D-1.8-1). About 60% of the estimated inventory is contained within fine facies sediment deposits, and 40% is contained in coarse facies deposits. The total estimated mass of anthropogenically-added chromium in sediment deposits in the Mortandad watershed is about 195 kg (430 lb) (Table D-1.8-1), which is <1% of the amount reported to have been released into Sandia Canyon (an average of 35.9 lb/d from 1950 to the mid-1970s or >100,000 lb; LANL 2006, 91987, p. 3).

A comparison of chromium concentrations with particle-size data indicates that the highest concentrations are in samples with high silt and clay content in reach E-1FW, indicating an affinity for fine-grained sediment particles, as seen with radionuclides (Figure 7.1-22). However, the highest concentration downcanyon in E-1W is in a sample of coarse facies sediment with relatively low silt and clay content. The high concentration in a coarse sediment sample in E-1W is interpreted to represent streambed sediment that was in direct contact with chromium-bearing effluent, as discussed for cesium-137 in M-2W in Section 7.1.1-5.

Chromium analyses obtained from the active channel between the TA-50 RLWTF outfall and the sediment traps in 1979 (Ferenbaugh and Gladney 1997, 93715) provide insights into both temporal and spatial trends in chromium concentration in Effluent and Mortandad Canyons. Figure 7.1-23 plots chromium results from 1979 as a function of distance from the RLWTF outfall and also shows average values from environmental surveillance samples (1992–2005) and active channel samples from the reach investigations (1998–2005). The 1979 data indicate much higher concentrations than at present and a progressive downcanyon decrease in concentrations, attaining present-day concentrations (below the background average) in reach M-3. The data indicate that chromium was being actively released into Effluent Canyon in 1979 or earlier and that by the early 1990s, little chromium was remaining in the active channel of Effluent or Mortandad Canyons downcanyon from the RLWTF outfall.

As with chromium, copper data indicate a clear source at TA-48, with maximum concentrations in the Mortandad watershed in reach E-1FW, and decreasing concentrations downcanyon. Average copper concentrations in fine facies sediment in E-1FW are roughly 5 times greater than in the next highest reach, E-1E, and remain above background averages through M-4 (Figure 7.1-20). Copper is not a COPC farther downcanyon. The spatial distribution of copper indicates additional sources into Ten Site Canyon from TA-35, with a local maximum in reach TS-2C below the outfalls from the TA-35 wastewater lagoons. Copper is not a COPC in TS-1W but is in TS-1C and downcanyon, indicating one or more sources at other TA-35 SWMUs or AOCs. Additional sources of copper into the upper part of Mortandad Canyon from TA-03 and TA-48 are indicated by average concentrations in fine facies sediment that exceed the background average in reaches M-1W and M-1E. The M-1W data may indicate a source from

road runoff, as copper is reported to be a common contaminant associated with vehicles (Breault and Granato 2000, pp. 48–49).

Cyanide has a maximum concentration in sediment samples in reach MCW-2W, on San Ildefonso Pueblo land below TA-05 SWMUs or AOCs. This was the only detected result above the BV (1.37 mg/kg in sample CAMO-03-49844, vs. BV of 0.82 mg/kg), and additional samples were collected in 2005 to see if this result could be confirmed. Resampling of that location and additional samples from two nearby locations in the same geomorphic unit yielded results below the BV (0.14 to 0.19 mg/kg, samples CAMO-05-63588, CAMO-05-63608, and CAMO-05-63609). There is therefore no evidence of cyanide from Laboratory SWMUs or AOCs impacting sediments in the Mortandad watershed.

Iron data suggest releases from the same sources as for arsenic and chromium, although average concentrations are generally within the background range and background variations at least partially affect the results. Only one reach, M-1E, has average concentrations in fine facies sediment slightly greater than the BV, indicating collocation with arsenic and chromium (Figure 7.1-20). Average concentrations in E-1FW and TS-2E are above background averages and suggest additional sources into the head of Effluent Canyon and into Ten Site Canyon, although average concentrations of iron are also greater than background averages in M-5W, downcanyon from significant Laboratory-derived contamination. The M-5W iron results above the BV are interpreted to represent a locally elevated background, as also found in Cañada del Buey, the next canyon to the south (Drakos et al. 2000, 68739).

Lead data indicate multiple sources in the upper parts of Effluent, Mortandad, and Ten Site Canyons. The average concentrations of lead in fine facies sediment are above the sediment BV in reaches E-1FW, M-1C, and M-1E and close to the BV in M-1W and TS-1C (Figure 7.1-20). Lead concentrations decrease downcanyon from these areas, and lead is not identified as a COPC downcanyon from M-4E. Lead is a common contaminant found below roads and other developed areas, and one source is leaded gasoline (Walker et al. 1999, 82308, p. 364; Breault and Granato 2000, 82310, p. 48; Callender and Rice 2000, 82307, p. 232). The distribution of lead in the Mortandad watershed suggests runoff from developed areas is one source, although releases from Laboratory SWMUs or AOCs is also possible, particularly from sites like TA-48 where the sediment data indicate releases of other metals (e.g., arsenic, chromium, copper, mercury, and vanadium).

Manganese data suggest releases from one or more sources in the Mortandad watershed, although background variability appears to be responsible for at least some of the results above the BV. Average manganese concentrations in fine facies sediment are greater than the BV in reaches M-1E and E-1W (Figure 7.1-20), suggesting releases from TA-48 and possibly TA-55. These are also reaches with relatively high concentrations of manganese in surface water (Section 7.2.2.1). Manganese is also elevated relative to background averages in E-1FW, E-1E, and TS-3. Although the elevated concentrations in E-1FW and E-1E suggest releases from one or more outfalls into Effluent Canyon, the TS-3 results apparently record background variations because manganese is not a COPC in the TS-2 reaches, closer to potential contaminant sources.

Mercury data indicate multiple sources in the Mortandad watershed, with the TA-50 RLWTF outfall into Effluent Canyon reach E-1E and the TA-35 sand filter-bed outfall into Ten Site Canyon reach TS-2E being most important (Figure 7.1-20). These two reaches and reaches M-2W and M-2E in Mortandad Canyon downcanyon from Effluent Canyon have average mercury concentrations in fine-grained sediment deposits greater than the BV, and several other reaches have averages greater than the background average, including E-1FW, M-1W, M-1E, and TS-2C. Data from these reaches indicate additional sources of mercury at TA-03, TA-35, and TA-48. Concentrations generally decrease downcanyon, and mercury was not identified as a COPC east of M-4.

Perchlorate data from sediment are relatively sparse but indicate a recognizable source at the TA-50 RLWTF outfall into reach E-1E, consistent with effluent discharge records, and transport downcanyon into M-4 (Figure 7.1-20). Perchlorate was not detected in Effluent Canyon upcanyon from the RLWTF outfall or in Ten Site Canyon but was detected in every reach between the RLWTF outfall and the east end of M-4. The absence of detected perchlorate in sediment in Ten Site Canyon contrasts with its detection in a borehole in Pratt Canyon, as discussed in Section 7.2.2.1, that indicates releases from the former TA-35 WWTP. Perchlorate concentrations in sediment in the Mortandad watershed are low, with a maximum measured concentration of 0.959 mg/kg in reach M-2W (sample CAMO-01-0072). Average concentrations suggest a secondary peak in reach M-4E (Figure 7.1-20), although this is not considered to be reliable because of the low sample numbers and high frequency of nondetects (67% nondetects between the RLWTF outfall and the east end of M-4). The low-detection frequency and low concentrations in sediment samples are consistent with the high solubility of perchlorate and indicate a relatively small inventory in the near-surface sediment deposits in Mortandad Canyon.

Selenium is a COPC that exceeds the wSAL in stormwater in the Mortandad watershed and that NMED has requested be included in biota evaluations (NMED 2005, 92084). Selenium has been identified as a COPC in sediment in all reaches in the watershed except one (M-5W) and has detected results greater than the sediment BV of 0.3 mg/kg in most of the other reaches (except M-6, MCW-2N, and TS-1W, where nondetect values exceed the BV). Understanding the sources and distribution of selenium in the Mortandad watershed is complicated by elevated detection limits in many samples and by local background concentrations that appear to be greater than the BV. Selenium detection limits as high as 11.5 mg/kg have been provided by analytical laboratories for sediment samples from the Mortandad watershed, which results in large uncertainties in estimates of average concentrations, as shown in Figure 7.1-20. Elevated background levels are indicated by data from units with little or no evidence of Laboratory contamination, such as five samples from the area designated as f2?(Qt?) in reach M-4E. Selenium concentrations from this geomorphic unit average 0.37 mg/kg and range from 0.26 to 0.51 mg/kg. Data from the adjacent watershed of Cañada del Buey also indicate an elevated local background for selenium, and sediment from drainages with no upgradient SWMUs or AOCs has yielded selenium results as high as 1.2 mg/kg (Drakos et al. 2000, 68739). These data indicate local background concentrations of selenium significantly above the BV of 0.3 mg/kg and at least as high as 1.2 mg/kg. Review of the maximum detected selenium concentrations shows that they are geographically dispersed and do not indicate a clear Laboratory source, contrasting with the distribution of other inorganic chemicals discussed in this section. For example, the four detected selenium results that exceed 1 mg/kg (range of 1.1 to 1.6 mg/kg) were obtained from four different reaches (E-1E, M-1E, TS-1E, and TS-2C). Therefore, although selenium data indicate the possibility of releases from Laboratory SWMUs or AOCs, if releases occurred, they were apparently small in relation to local background levels; natural background variations may account for much or all of the elevated selenium results.

Thallium is a potentially important COPC for evaluating ecological risk, as discussed in Section 8.1. Thallium data suggest relatively small releases into Effluent Canyon from the TA-50 RLWTF and rapid downcanyon attenuation. Only five detected thallium results are above the BV of 0.73 mg/kg: three in reach E-1E and two in M-2W. In both reaches, the average thallium concentration in fine facies sediment is above the background average but well below the BV (Figure 7.1-20). Thallium is a COPC in only three other reaches (M-5E, TS-1W, and TS-1C) and only because detection limits for some samples are greater than the BV.

Vanadium is a potentially important COPC for evaluating ecological risk, as discussed in Section 8.1, and vanadium data indicate releases from multiple Laboratory sources. The average concentrations of vanadium in fine facies sediment are greater than the BV in reaches M-1E and E-1FW (Figure 7.1-20), both downcanyon from outfalls at TA-48 and indicating releases from this site into Mortandad Canyon and

into the head of Effluent Canyon. Concentrations attenuate rapidly downcanyon from these reaches, and vanadium is not a COPC in either E-1E or M-2W. Vanadium concentrations are also elevated in Ten Site Canyon, with average concentrations being close to the BV in reach TS-2E, downcanyon from the TA-35 sand filter-bed outfall. Elevated concentrations in TS-1W, TS-1C, and TS-2W suggest additional sources into Ten Site Canyon from TA-50 and TA-35.

Zinc is a potentially important COPC for evaluating ecological risk, as discussed in Section 8.1, and zinc data indicate multiple sources in the Mortandad watershed. The highest average zinc concentrations in fine facies sediment are in reach M-1W at the head of Mortandad Canyon, and zinc concentrations progressively decrease downcanyon (Figure 7.1-20). Reach M-1W receives runoff from large areas of paved roads and parking lots, and zinc is commonly found in urban runoff; one important source for zinc is tire-wear particulates (Walker et al. 1999, 82308, p. 364; Breault and Granato 2000, 82310, p. 49; Callender and Rice 2000, 82307, p. 232). Similarly, the highest average concentrations of zinc in the Los Alamos and Pueblo watershed were found in the upper parts of Acid and DP Canyons, which also receive runoff from large paved areas (LANL 2004, 87390, p. 7-14). The average concentration of zinc in M-1W, about 85 mg/kg, is less than that found in reaches in upper Acid and DP Canyons, 100-130 mg/kg. A secondary maximum for zinc occurs in reach E-1FW at the head of Effluent Canyon, indicating a source in runoff from developed areas at TA-48 and/or releases from outfalls. In comparison to upper Mortandad and Effluent Canyons, Ten Site Canyon has lower levels of zinc in relation to background levels, with average concentrations in fine facies sediment being greater than the background average but less than the BV (Figure 7.1-20).

In summary, the sediment data indicate that inorganic chemicals in the Mortandad watershed have multiple sources, including Laboratory SWMUs or AOCs, runoff from developed areas, and naturally occurring soils. TA-48 is apparently the most important source for several metals, including arsenic, chromium, copper, vanadium, and possibly iron, and included releases into Mortandad Canyon and particularly into the head of Effluent Canyon. The TA-50 RLWTF outfall into Effluent Canyon is the most important source for mercury, perchlorate, and possibly thallium. The former sand filter-bed outfall from TA-35 into Ten Site Canyon is apparently a secondary source for several metals, such as arsenic, chromium, mercury, and vanadium. Runoff from developed areas is apparently the most important source of zinc and possibly lead. Some of the variations in concentrations of inorganic chemicals are also attributable to background variations, such as iron in reach M-5W and perhaps elsewhere and selenium in many reaches. Concentrations generally decrease downcanyon from the sources, and in some cases the contaminants are largely contained in sediment deposits near the sources, such as chromium in the upper part of Effluent Canyon. Remobilization of these chemicals by erosion will result in a progressive downcanyon shift of the inventory and accompanying decreases in concentrations, as discussed for radionuclides.

7.1.3 Organic Chemicals in Sediments

Two organic chemicals detected in sediments in the Mortandad watershed have maximum results greater than residential SSLs and are more important for assessing potential human health risk: the PCB Aroclor-1264 and the PAH benzo(a)pyrene. Additional organic chemicals detected in sediment samples are important for assessing potential ecological risk (e.g., bis(2-ethylhexyl)phthalate, di-n-butylphthalate, DDT[4,4-], and endrin aldehyde), for understanding relations between COPCs in water and sediment (e.g., bis(2-ethylhexyl)phthalate), or for understanding potential off-site transport onto San Ildefonso Pueblo land (e.g., acenaphthene, acetone, and bis(2-ethylhexyl)phthalate). These organic chemicals are derived from a variety of sources, including Laboratory SWMUs or AOCs and runoff from roads and other developed areas, as indicated by their spatial distribution (discussed below). Once in the canyon bottoms, most of these organic chemicals will adsorb to sediment particles and organic matter, and their

subsequent fate and transport by fluvial processes are expected to be similar to that for the radionuclides, which were discussed in detail in Section 7.1. Similar to some of the radionuclides, the organic chemicals discussed here have relatively short environmental half-lives associated with biodegradation and/or volatilization in the environment. Therefore, the concentrations will decrease over time unless contaminants are added to the canyon bottoms (such as from road runoff). However, the degradation rates are not well constrained and will vary with local environmental conditions.

This section focuses on spatial variations in organic chemicals in the Mortandad watershed, and supporting information is included in Appendix D. Table D-1.7-2 presents average concentrations in each reach for organic chemicals that are discussed in this section, substituting one-half of the detection limit for nondetected sample results. Table D-1.7-2 also presents the upper and lower bounds on these averages, using either the detection limit or zero for nondetects, respectively. This table indicates that on average, concentrations of these organic chemicals are lower in coarse than in fine facies sediment, and the discussions and figures in the following sections focus on data from fine facies sediment. Table D-1.7-2 also indicates that considerable uncertainty exists in the average concentration of organic chemicals in some reaches because of elevated detection limits.

7.1.3.1 PCBs

PCBs have low solubilities and a strong affinity for organic material and sediment particles (Chou and Griffin 1986, 83419). PCBs were widely used in electric transformers and other industrial applications (e.g., Walker et al. 1999, 82308, pp. 364–365), and their wide use is consistent with their spatial distribution in sediments in the Mortandad watershed. Figure 7.1-24 presents average concentrations of Aroclor-1260 and Aroclor-1254 in fine facies sediment in the Mortandad watershed, substituting one-half of the detection limit for nondetected sample results and showing upper and lower bounds on these averages. These data indicate that PCBs come from multiple sources in the watershed and that concentrations generally decrease downcanyon from these sources, as discussed below.

Aroclor-1260 has been detected in almost every reach in Effluent and Ten Site Canyons and in Mortandad Canyon as far east as M-4 but not farther downcanyon or in the unnamed tributary canyon that heads in TA-05. Aroclor-1260 has the highest average concentrations in reaches TS-1W and TS-1C, indicating one or more sources from TA-50 and possibly TA-35 into the upper part of Ten Site Canyon (Figure 7.1-24). These are also the only reaches with maximum concentrations above residential SSLs (1.37 and 1.3 mg/kg vs. an SSL of 1.12 mg/kg). Average concentrations of Aroclor-1260 decrease rapidly downcanyon in Ten Site Canyon. The data indicate additional sources into Effluent and Mortandad Canyons but at lower levels than in Ten Site Canyon.

Aroclor-1254 has a lower frequency of detection and was detected at lower concentrations and in fewer reaches than Aroclor-1260. The spatial distribution of Aroclor-1254 is somewhat different than for Aroclor-1260. Aroclor-1254 has the highest average concentrations in reach E-1FW (Figure 7.1-24), indicating the most important source for this PCB is TA-48, and concentrations decrease rapidly downcanyon in Effluent Canyon. Additional minor sources are indicated in upper Ten Site Canyon above reach TS-1W.

7.1.3.2 PAHs

PAHs have a range of chemical properties with some being less volatile and less soluble, and these chemicals are more likely to become adsorbed to and persist in sediments (Neff 1979, 83420). Some PAHs, such as naphthalene, are relatively volatile and should have the lowest affinity for sediments, whereas others, such as benzo(a)pyrene, are less volatile and less soluble and have a stronger affinity

for sediments. The different PAHs also have somewhat different spatial distributions in the Mortandad watershed, indicating different sources, as discussed below. Considerable uncertainty exists in the average concentrations of PAHs in some reaches because of elevated detection limits in data obtained from the SVOC analytical suite (method SW-846:8270C), although detection limits and associated uncertainties are lower in reaches with data obtained from the PAH analytical suite (method SW-846:8310).

Benzo(a)pyrene is the only PAH in the Mortandad watershed with concentrations above residential SSLs and has been detected in most reaches in Effluent and Ten Site Canyons and in Mortandad Canyon as far east as M-4 but not farther downcanyon or in the unnamed tributary canyon that heads in TA-05. Benzo(a)pyrene has the highest average concentrations at the head of Mortandad Canyon in reach M-1W, downcanyon from large paved areas and a major road in TA-03 (Diamond Drive) (Figure 7.1-25), consistent with a primary source in runoff from developed areas. Drainage from tar roofs is another possible source of benzo(a)pyrene and other PAHs in runoff from developed areas. A clear association between benzo(a)pyrene and runoff from developed areas was also seen in the Los Alamos and Pueblo watersheds (LANL 2004, 87390, p. 7-16), where average concentrations are up to several times higher than in the Mortandad watershed (the average concentration in fine facies sediment in reach AC-1 at the head of Acid Canyon is approximately 2.3 mg/kg, compared with approximately 0.7 mg/kg in M-1W). Benzo(a)pyrene is also notably elevated in reaches TS-1C and TS-1E in upper Ten Site Canyon (average of approximately 0.5 mg/kg, Figure 7.1-19), indicating a source from developed areas at TA-35 and/or TA-50. Lower concentrations are present in Effluent Canyon (average of approximately 0.2 mg/kg, Figure 7.1-19) and farther downcanyon in Mortandad Canyon.

Acenaphthene is the only PAH detected east of reach M-4, in reach M-5E, and the maximum detected concentration in the Mortandad watershed is also in M-5E (1.8 mg/kg). The apparent spatial distribution of acenaphthene is very irregular (Fig. 7.1-25), and the apparently elevated concentrations in M-5E are not considered reliable because of the absence of other evidence for significant transport of other contaminants this far downcanyon (Section 7.1.1.6). In addition, the elevated concentrations of acenaphthene in M-5E were obtained from the SVOC analytical method in 2000, and subsequent sampling in 2004 using the PAH method, with lower detection limits (0.025 mg/kg), did not provide any detected results. Interpretation of the acenaphthene results in upcanyon reaches is complicated by elevated detection limits and a high frequency of nondetects in many reaches, although the elevated results in M-1C are considered reliable because they were obtained with the PAH method, and the M-1C data had a relatively high-detection frequency (50%). These data therefore indicate a source for acenaphthene in upper Mortandad Canyon, such as runoff from developed areas as inferred for benzo(a)pyrene, and perhaps other less important sources in Effluent and Ten Site Canyons (Figure 7.1-25).

7.1.3.3 Other SVOCs

Besides PAHs, several other SVOCs are important in the Mortandad watershed for assessing potential human health or ecological risk, understanding sources of COPCs in water, or assessing potential transport off-site onto San Ildefonso Pueblo land. Sources and average concentrations of these SVOCs are typically uncertain, as discussed below.

Bis(2-ethylhexyl)phthalate was identified by ECORSK9 modeling as being the most important COPEC for the Mexican spotted owl, a T&E species (Gonzales et al. 2006, 93786). This SVOC also exceeds drinking water standards and has been detected in sediment samples collected on San Ildefonso Pueblo land. As shown in Figure 7.1-26, bis(2-ethylhexyl)phthalate displays no clear spatial trends in fine facies sediment, and the estimated average concentrations have much uncertainty associated with high frequencies of

nondetects (82% in sediment samples in the watershed) and with detection limits that are similar to reported detected values. Anomalies in the data set also indicate many of the detected values are suspect and/or do not represent releases from Laboratory SWMUs or AOCs. For example, five out of nine samples from reach M-6 are reported as detects, and the estimated average concentration here is similar to in upcanyon reaches closer to potential sources (Figure 7.1-26), but there are no detects in the next two upcanyon reaches (M-5W and M-5E) and no evidence for transport of other COPCs as far downcanyon as M-6. EPA has identified bis(2-ethylhexyl)phthalate as a common laboratory contaminant (EPA 1989, 8021, p. 5-16), which may explain some of the results. Therefore, although the available bis(2-ethylhexyl)phthalate data indicate the possibility of releases from SWMUs or AOCs, because of uncertainties in the data set, no sources can be clearly identified, and concentrations in sediment in the watershed are poorly constrained.

Di-n-butylphthalate was identified by ECORSK9 modeling as being the most important COPEC for the western bluebird and southwestern willow flycatcher, a T&E species (Gonzales et al. 2006, 93786). This SVOC has a high frequency of nondetects in sediment samples from the Mortandad watershed (99.5% nondetects) and was detected only in three reaches (MCW-2N, TS-1W, and TS-1C). As with bis(2-ethylhexyl)phthalate, di-n-butylphthalate displays no clear spatial trends in fine facies sediment (Figure 7.1-26), and the estimated average concentrations have much uncertainty associated both with the low detection frequency and detection limits that are similar to reported detected values. EPA has also identified di-n-butylphthalate as a common laboratory contaminant (EPA 1989, 8021, p. 5-16). Therefore, although the available di-n-butylphthalate data indicate the possibility of releases from SWMUs or AOCs, because of uncertainties in the data set no sources can be clearly identified, and concentrations in sediment in the watershed are poorly constrained. It is possible that the detected values at least in part reflect artifacts of the laboratory analyses (e.g., false positives).

7.1.3.4 Pesticides

Several pesticides in sediments have been identified as potentially important in assessing ecological risk in the Mortandad watershed. These organic chemicals have low solubilities and a strong affinity for organic material and sediment particles (Pionke and Chesters 1973, 83423; Nowell et al. 1999, 83422). The spatial distribution of pesticides in sediments in the Mortandad watershed indicates that these analytes have multiple sources at the Laboratory, which is consistent with their expected dispersed use in pest-control efforts. However, understanding their spatial distribution and sources is in part complicated by a high frequency of nondetects and detected concentrations close to detection limits. As two examples, Figure 7.1-27 presents average concentrations of DDT and endrin aldehyde in fine facies sediment in the reaches, substituting one-half of the detection limit for nondetected sample results and showing upper and lower bounds on these averages.

DDT is the pesticide with the highest aquatic HQ in the Mortandad watershed. It was detected at low concentrations in many reaches, although it has a relatively low detection frequency in the watershed (84% nondetects). The data suggest that the highest concentrations are in Mortandad Canyon from Effluent Canyon to reach M-3W, although much uncertainty is present associated with the influence of nondetects (Figure 7.1-27). Ten Site Canyon has detects only in reach TS-3 and not in upcanyon reaches closer to sources, indicating the apparent spatial patterns may not be reliable. Effluent Canyon reach E-1FW also has no detects of DDT, although downcanyon reaches do.

Endrin aldehyde is the pesticide with the highest terrestrial HQ in the Mortandad watershed. Endrin aldehyde has a low frequency of detection in sediment samples in the Mortandad watershed (97% nondetects) and was detected only in reaches E-1E, M-1C, M-2W, and M-3. Sources for endrin aldehyde are uncertain, and its spatial distribution does not display clear trends, showing the highest

concentrations in reaches M-2W and M-3 (Figure 7.1-27). Average concentrations are also uncertain because of detected values that are similar to the detection limits.

7.1.3.5 VOCs

VOCs have been detected in many reaches within the Mortandad watershed at low concentrations, but their spatial distribution is irregular and it is not certain to what degree the reported detects represent releases from SWMUs or AOCs or instead artifacts of the analyses (e.g., false positives). Detects in downcanyon reaches (M-5W and M-5E), at similar or greater concentrations than in upcanyon reaches closer to potential sources, indicate that at least some of these results do not represent releases from the Laboratory. Examples are discussed below for acetone, benzene, and methylene chloride.

Acetone has been detected in most reaches within the Mortandad watershed, with the highest average concentrations in fine facies sediment in M-1E and E-1FW below TA-48, suggesting releases from this TA (Figure 7.1-28). Acetone data also suggest releases from one or more sites into Ten Site Canyon, with estimated highest average concentrations in TS-1C and TS-2E. However, acetone concentrations are also relatively high in M-5W and M-5E, and it seems unlikely that the M-5W and M-5E data represent transport of acetone from Laboratory sites because these reaches are downcanyon of significant transport of radionuclide COPCs (Section 7.1.1.6). EPA has identified acetone as a common laboratory contaminant (EPA 1989, 8021, p. 5-16), and some of the results may represent false positives.

Benzene has also been detected downcanyon in M-5E in a single sample (CAMO-04-53325, 0.0006 mg/kg), at a concentration similar to in upcanyon reaches closer to potential sources. Of the nine detects in sediment samples from the Mortandad watershed (4% detection frequency), six are from Ten Site Canyon, with a maximum from TS-2E (CAMO-04-53394, 0.0008 mg/kg). The benzene data therefore indicate possible releases from Laboratory sites into Ten Site Canyon, although the detect in M-5E indicates that at least some of the data represent artifacts of the laboratory analyses.

Methylene chloride has been detected in five reaches in the Mortandad watershed (M-3, M-4, M-5W, M-5E, and TS-1C), and the maximum concentrations and the highest frequency of detects are in reaches M-5W and M-5E (Figure 7.1-28). Other reaches closer to potential sources have only single detects, at lower concentrations. The apparent spatial distribution of methylene chloride is therefore inconsistent with releases from Laboratory sites and subsequent downcanyon transport by floods. EPA has identified methylene chloride as a common laboratory contaminant (EPA 1989, 8021, p. 5-16), and these data largely or entirely represent artifacts of the laboratory analyses.

7.2 Conceptual Models for Hydrology and Contaminant Transport in Groundwater

The hydrology of the Mortandad watershed is described in Section 7.2.1 and includes surface water, alluvial groundwater, pore water in the upper vadose zone, intermediate-perched water, and regional groundwater. Contaminant distributions and transport processes are described in Sections 7.2.2 and summarized in Section 7.3.

7.2.1 Watershed Hydrology

The Mortandad watershed heads in the central part of the Pajarito Plateau in TA-03 and extends east southeast for 15.8 km (9.8 mi) to the Rio Grande (Plate 1). The watershed has a catchment area of about 15.5 km^2 (6 mi^2), which is relatively small compared with larger watersheds that head in the mountains, such as the Los Alamos and Pueblo Canyons watershed. The Mortandad watershed has no naturally perennial reaches. As a result, the surface water, alluvial groundwater, unsaturated zone and

intermediate-perched zone hydrology of the Mortandad watershed is largely controlled by the location and discharge volumes of anthropogenic water sources and by runoff from developed (e.g., paved) Laboratory technical areas. The subsequent distribution of surface water, sediments, groundwater, and contaminants is strongly influenced by the canyon geology and topography.

The Mortandad drainage heads entirely within the upper units of the Tshirege Member of the Bandelier Tuff. From its headwaters, the stream channel drops about 300 m (1000 ft) over a 13-km (8-mi) passage to the bluffs above White Rock Canyon, with an additional 245-m (800-ft) drop in elevation along the last ~3 km (~1.8 mi) of steep channel to the Rio Grande. Along the 13-km (8-mi) segment of shallower gradient, the stream channel cuts progressively down section through the Tshirege Member of the Bandelier Tuff, Cerro Toledo deposits, the Otowi Member of the Bandelier Tuff, and perhaps some minor amounts of Puye Formation fanglomerate that wedge out eastward on top of Cerros del Rio lava flows. The steep channel near the Rio Grande cuts through resistant Cerros del Rio lavas capping poorly consolidated stream gravels (Totavi Lentil) and Santa Fe Group sediments. These relations are illustrated in the conceptual hydrogeologic cross section in Figure 7.0-1.

For the purposes of the following hydrologic discussion, the Mortandad Canyon watershed on Laboratory property is subdivided into five canyon segments based on their hydrogeologic characteristics. The locations of these hydrologic segments are shown in Figure 7.2-1. These five segments include the

- Upper Mortandad Canyon hydrologic segment extending from the headwaters near Diamond Drive to the confluence with Effluent Canyon,
- Effluent Canyon hydrologic segment extending from the headwaters of Effluent Canyon to the confluence with Mortandad Canyon,
- Middle Mortandad Canyon hydrologic segment extending from the confluence with Effluent Canyon to the confluence with Ten Site Canyon,
- Ten Site Canyon hydrologic segment extending from the headwaters of Ten Site Canyon to the confluence with Mortandad Canyon, and
- Lower Mortandad Canyon hydrologic segment property extending from the confluence of Ten Site Canyon to the eastern Laboratory boundary.

7.2.1.1 Surface Water Hydrology

The conceptual model for surface water hydrology is based on gaging station data, outfall discharge records, and visual observations. Figure 7.2-1 shows the locations and modes of surface water occurrences throughout the watershed and the current locations of Laboratory NPDES outfalls and surface water gages. Canyon reaches defined for sediment sampling and their designations are also shown since they provided the basis for documenting visual observations of surface water occurrence.

The primary sources of surface water in the Mortandad watershed, aside from seasonal runoff and snowmelt, are currently five NPDES outfalls (Figure 7.2-1):

- TA-03-29, CMR Building (NPDES outfall EPA03A-021)
- TA-03-2274, Sigma Building (NPDES outfall EPA03A-022)
- TA-55-6, Plutonium Facility Complex (NPDES outfall EPA03A-181)
- TA-50-1, Radioactive Liquid Waste Treatment Facility (NPDES outfall 051)
- TA-35-124, Large Generator (NPDES outfall EPA03A-160)

The TA-03 outfalls consist of treated water associated with cooling at the CMR and Sigma Buildings and provide seasonal, intermittent discharges (generally April or May through October) to the upper Mortandad Canyon hydrologic segment above reach M-1W. The TA-55 outfall provides intermittent discharge of treated cooling water to upper Effluent Canyon above reach E1-W. Historically, each outfall discharged about 38 L/min ($6.3x10^{-4}$ m^3/s) (LANL1997, 57236), but discharges are discontinuous, variable, and seasonal. The TA-50 outfall consists of treated effluent discharges from the RLWTF into reach E-1E. Since 1997, the RLWTF discharges have averaged approximately 37.4 cubic meters per day (m^3/d). However, these discharges have decreased significantly in recent years from an average 63.7 m^3/d L/d in 1998 to an average 17.3 m^3/d in 2006 (through September 4, 2006). The TA-35 outfall discharges cooling tower blowdown associated with a large generator to Ten Site Canyon above reach TS-1W. These outfalls combined provide a significant component of surface water flow in the watershed beyond that produced by naturally occurring runoff and snowmelt. Annual discharge totals for the Mortandad outfalls from 2004 to 2005 are shown in Table 7.2-1 (LANL 2004, 94068; LANL 2005, 94073).

A total of five streamflow gaging stations are operated within the Mortandad watershed (Figure 7.2-1), from which data are regularly reported (Shaull et al. 2005, 92225; Shaull et al. 2006, 93735). Gage E200 is located in the uppermost portion of the middle Mortandad Canyon hydrologic segment approximately 30 m (100 ft) below the confluence of Effluent Canyon and 230 m (755 ft) below the TA-50 RLWTF outfall. This gage records the sum of natural runoff plus RLWTF effluent and TA-55 outfall discharges. Gage E202 is located at the boundary between the middle and lower Mortandad Canyon hydrologic segments upstream of the sediment traps at the Ten Site confluence. This gage only occasionally measures flow during extreme runoff events and records no flow most of the time. Gage E2015 is located in the Ten Site Canyon hydrologic segment approximately 400 m (1310 ft) upstream from E202. This gage has recorded only occasional minor intermittent flows since October 2000. Gage E203 is located in the lower Mortandad Canyon hydrologic segment at the outlet to sediment trap #3, approximately 260 m (850 ft) downstream from E202, and gage E204 is located in the lower Mortandad Canyon hydrologic segment approximately 15 m (50 ft) upstream from the Laboratory/San Ildefonso Pueblo boundary. Gage E203 has been continuously dry since October 1996 except for two recent sediment trap overflow events on August 24, 2005 (Shaull et al. 2006, 93735, pp. 44-45,) and August 25, 2006. Gage E204 has been continuously dry since October 1993, but there has been no known flow at San Ildefonso boundary since RLWTF discharges began in 1963. Table 7.2-2 shows the number and percentage of days with recorded flow at each streamflow gaging station. These data show the effects of infiltration losses on surface water between the middle and lower Mortandad Canyon hydrologic segments. Whereas gage E200 recorded flow for 75% of the days of record, E202 recorded flow for only 14% of the days of record, while E203 and E204 have been continuously dry during the period of record.

Since gage E200 is the uppermost reported streamflow gage in the watershed, a comparison of outfall discharges to the streamflow measured at gage E200 was made to assess the magnitude of the component of outfall discharges to total flow in the canyon (Figure 7.2-2). These data illustrate a variable relation between the volumes of outfall discharges and recorded flow at E200. The RLWTF is the only outfall whose flow reaches gage E200; flow from the others stops upcanyon, while the TA-35 effluent enters Mortandad Canyon below the gage (actually never making it out of Ten Site Canyon) and does not contribute to streamflow at E200. Data from 2004 and 2005 show streamflow significantly exceeding outfall volumes for the four contributing outfalls; these years had fairly normal natural runoff volumes. The RLWTF outfall percentage of flow at E200 was 4% and 9% during 2004 and 2005, respectively.

Surface water occurrences were determined from a series of field observations made during site visits to the various sediment sampling reaches in the canyon between June 2003 and September 2005 (Reneau, 2005). Canyon reaches with surface water observations are subdivided into ranges of percentage of observations with surface water present. Reaches identified in 100% of the observations are considered

"perennial" where water flow is continuous throughout most of the year. Reaches identified in 50%–99% of the observations are considered "intermittent" where the stream channel is predominantly dry throughout much of the year but have some extended periods of flow from snowmelt runoff, spring discharge, or groundwater discharge associated with high groundwater levels. Reaches identified in 1%-49% of the observations are considered "ephemeral" where the stream channel is predominantly dry throughout most of the year but may experience short periods of flow (i.e., hours to days) in response to storm events, particularly summer thunderstorms.

Approximately 87% of the Mortandad watershed upstream from the boundary with San Ildefonso Pueblo burned in the Cerro Grande fire of 2000 (BAER 2000, 72659). However, the burn was of low intensity and little to no change is surface water flow was recorded in the years immediately following the fire. Gage records indicate similar peak discharges before and after the fire (Shaull et al. 2003, 76042).

Upper Mortandad Canyon Hydrologic Segment

In upper Mortandad Canyon, above the confluence of Effluent Canyon, welded tuffs underlying the stream channel are relatively impermeable and limit the amount of infiltration along the stream channel. Persistent surface water originates primarily at TA-03 from runoff events (snowmelt and rainfall) and from seasonal outfall discharges from noncontact cooling water. Reach M-1W is indicated in Figure 7.2-1 as a perennial reach with surface water present during 100% of the observations made during the 2003-2005 surveillance period. Reach M-1W is downstream from NPDES outfall EPA03A-021 from the CMR Building in TA-03 and also receives runoff from extensive paved areas at the head of the watershed. Water was always observed in bedrock pools in the east part of M-1W and was usually observed in a bedrock area closer to the outfall and in the middle of the reach downstream from a headcut into alluvium where a small cattail wetland is supported. Plunge pools occur where the stream channel becomes steeper as the drainage incises into the upper part of Tshirege unit Qbt 2. Intermittent flow conditions exist below reach M-1W, as indicated by observations in reaches M-1C (below TA-48) and M-1E. A small cattail wetland exists adjacent to the stream channel below TA-48, and cattail wetlands are also present in reach M-1E where the stream has a bedrock channel as the canyon steepens eastward. Relatively deep and persistent bedrock pools are present downstream from reach M-1E. Historically, other outfalls from TA-48 have also contributed to surface water in this canyon segment. No gage is located within this canyon segment, but 79% of the observations made in reach M-1E indicate the intermittent presence of surface water there while 50% of the observations in reach M-1C indicated intermittent water associated with a fluctuating water table in the alluvium.

Effluent Canyon Hydrologic Segment

In Effluent Canyon, welded tuff bedrock underlying the stream channel limits infiltration along the stream channel. Intermittent flow occurs in reach E1F-W with surface water present during 75% of the observations. Here, water is fed by storm runoff that supports willows and cattails. Perennial flow is indicated in reaches E-1W (fed by the TA-55 outfall) and E-1E (fed by the TA-55 and TA-50 outfalls). Surface water was present during 100% of the observations made in these reaches between 2003 and 2005.

The TA-50 RLWTF has discharged to Effluent Canyon since 1963 at NPDES-permitted outfall EPA 051. Annual effluent discharge volumes have ranged from a high of 60.28 million liters (60,280 m^3) in 1968 to 6.93 million liters (6,930 m^3) in 2005 (Table 2.1-1 and Figure 2.1-1). Discharges are released from two 79,000-L (79-m^3) holding tanks. Effluent is released from one tank at a time when full. Timing of releases is variable, ranging from over 2 weeks between releases to daily releases over several consecutive days. Usually only one release occurs during a day, but occasionally two or three releases are made in a single

day. Between 1997 and September 2006, releases occurred an average of 3 d/wk. Historically, seasonal variability in discharge volumes has been significant, but quarterly release volumes have been relatively consistent since 2005 (Figure 7.2-3).

Effluent Canyon also receives stormwater runoff from portions of TA-48, TA-55, and TA-35, which contributes to a small wetland at the head of the canyon between TA-48 and the discharge point for the TA-50 outfall.

Middle Mortandad Canyon Hydrologic Segment

From west to east in the middle Mortandad Canyon hydrologic segment, bedrock becomes progressively less welded and more permeable, and canyon-bottom alluvium thickens. Surface flow generally infiltrates in the eastern part of this segment. Outfall discharges from Effluent Canyon are a major source of surface water to the middle Mortandad Canyon hydrologic segment below the confluence with Effluent Canyon and above the confluence with Ten Site Canyon (Figure 7.2-2). These discharges comprise a significant percentage of the flow at gage E200, which measures surface flow entering the middle Mortandad Canyon hydrologic segment from both the Effluent Canyon and upper Mortandad Canyon hydrologic segments. Based on visual observations between 2003 and 2005, indicating that surface water was present during 100% of the observations in reach M-2W, surface water flow in the middle Mortandad Canyon hydrologic segment is indicated as perennial in reach M-2W for a distance of approximately 570 m (1870 ft) below the Effluent Canyon confluence (fed by the TA-55 and TA-50 outfalls and road runoff) (Figures 7.2-1 and 7.0-1). Surface water in reach M-2W, however, is typically discontinuous, with stretches with no surface water, and water was present partly as bedrock pools and emergence from saturated alluvium rather than as a through-flowing stream. The region of surface water flow coincides with relatively thin alluvium in a channel underlain by the welded portions of Qbt 2. However, gage E200 has recorded flow for 75.4% of the days during its period of record since 1995, indicating that persistent surface flow is not uninterrupted in this canyon segment. Intermittent flow occurs in reach M-2E with surface water present as discontinuous flowing water and pools during 78% of the observations made during 2003–2005 surveillance period. No flow was observed below reach M-2E during the 2003–2005 observations, indicating the point below which water has infiltrated into the thickening canyon bottom alluvium or is lost to evaporation. Beyond reach M-2D, surface water is ephemeral in response to high discharge volumes or to upstream runoff. Only infrequently, generally following severe summer thunderstorms, does surface water exit the middle canyon. This is illustrated in Figure 7.2-4 which depicts the hydrographs for streamflow measured in reported gages during 2005 and 2006. The hydrograph for gage E202 shows that this gage recorded flow on only 11 of the 587 days of record during this period. Except for a larger flood event on August 24, 2005, during which the mean daily discharge was about 48 liters per second (L/s [1.7 cfs]), only minor flow events from about 1 to 6 L/s (0.04 to 0.2 cfs) mean daily discharge were measured at E202 during the 2005–2006 period (through August 14, 20/06).

Gage E200 provides the most consistent record of persistent flow in the watershed. A comparison of cumulative daily TA-50 effluent and gage E200 streamflow discharge volumes since 1997 is shown in Figure 7.2-5. From mid-1997 to 2000, the cumulative TA-50 discharges were roughly half of the total flow recorded at E200. Since 2001, the rate of discharge from TA-50 has declined while total runoff at E200 has increased. Notable flow increases were recorded at E200 in January 2002 and January-March 2004 associated with snowmelt or flood events. By August 2006, cumulative discharges from TA-50 were only about 19% of the cumulative total flow at E200 for the period from 1997 to August 2006.

A comparison of seasonal (quarterly) discharge volumes since 1997 for the TA-50 outfall and the E200 gage is shown in Figure 7.2-6. The streamflow volume for the quarter ending on 3/31/04 is literally off the chart in this figure. The total streamflow volume recorded at E200 during this quarter exceeded

175,000 m^3, which is nearly 5 times greater than the total flow at E200 in any other quarter since 1997. Otherwise, the highest quarterly streamflow totals are generally associated with spring snowmelt runoff and summer-fall monsoon rains while lower streamflow amounts are generally recorded in the winter, though several exceptions to this pattern are present (e.g., occasional high winter flows and low summer-fall flows). After the RLWTF discharges peaked in 1999, a subtle seasonal pattern of higher discharges in the summer and lower discharges in the winter is apparent for the TA-50 outfall, while the declining trend in discharge volume is clearly evident. The seasonal TA-50 percentage of E200 streamflow discharge is shown in Figure 7.2-7. Data from the second quarter of 1998 and the second and third quarters of 2000 were compromised by extended periods of equipment failure at E200 and are thus excluded from this graph. A clear pattern of seasonality for this parameter is not readily apparent from these data. Examining the extreme conditions for this parameter shows that the highest proportions of TA-50 contributions to total flow (exceeding 80%) occurred in the first and fourth quarters of 1997, the third quarter of 2000, the second quarter of 2004, and the first quarter of 2006. These occurrences are related to drought conditions leading to abnormally low inputs of naturally occurring runoff or snowmelt during these periods and not a regular seasonal variation. The lowest proportions of TA-50 contributions to total flow (less than 8%) occurred in the fourth quarter of 2001 and first quarter of 2002, the fourth quarter of 2003 and first quarter of 2004, and the first and third quarters of 2005. A relatively low proportion of TA-50 flow was also recorded in the fourth quarter of 2004 (about 14%). An inconsistent seasonal pattern is thus apparent during the winters of 2001–2002, 2003–2004, and 2004–2005 when higher runoff occurred leading to low relative contributions of outfall discharges to total flow. This analysis indicates that winter runoff is frequently (since 2001) a significant contributor to total surface flow in the upper and middle watershed.

The seasonal TA-50 outfall percentage of E200 flow since 1997 is summarized in Table 7.2-3. The mean and median percentages are nearly equal for the first and second quarters at about 41% and 47%, respectively. The third quarter exhibits the lowest proportion of TA-50 flow with mean and median percentages of about 23% and 25%, respectively, illustrating the effects of monsoonal rains to total flow in the watershed. The fourth quarter proportion of TA-50 flow has a mean percentage of about 34% but a median value of about 28%. These data suggest that overall, surface water flowing from the upper Mortandad Canyon hydrologic segment generated by naturally occurring runoff makes up a large percentage of E200 flow during the summer and fall. In addition, building cooling-water discharges from the CMR and Sigma Buildings at TA-03 may also contribute seasonally. The proportion of TA-50 flow during the summer and fall is only about one-fourth of the total streamflow, whereas during the winter and spring seasons, the TA-50 discharges comprise nearly half of the total flow recorded at gage E200. The annual averages clearly show the declining influence of the TA-50 outfall on surface flow in the watershed. Whereas in 1997 the TA-50 outfall comprised 63% of the flow recorded at E200, by 2005, its contribution was only 21%.

Ten Site Canyon Hydrologic Segment

Pratt Canyon is a small tributary to Ten Site Canyon, which is a tributary to Mortandad Canyon. Before 1963, Pratt Canyon received effluent from the TA-35 Waste Water Treatment Plant (Section 2.1). Purtyman (2002, 11787) reported that historical effluent discharges from Pratt Canyon to Ten Site Canyon were insufficient to reach Mortandad Canyon as surface flow.

Surface flow conditions in the Ten Site Canyon hydrologic segment are currently recorded at gage E2015, which is located near the mouth of canyon (Figure 7.2-1). As seen in Figure 7.2-4, mean daily flows recorded at E2015 seldom exceed 3 L/s (0.1 ft^3/s), and the gage is dry most of the time. As noted in Table 7.2-2, flow was recorded in this gage on only 11% of the days during its period of record (since 2000). Virtually all of this flow is attributed to runoff from paved areas, but the current TA-35 outfall (03A-160) releases into the head of Ten Site Canyon and may also contribute. As depicted in

Figure 7.2-1, surface water conditions range from intermittent in reaches TS-1W, TS-1C, and TS-2E to ephemeral in reaches TS-1E, TS-2W, and TS-2C. During the period of visual surveillance in 2003–2005, reaches TS-1W, TS-1C, and TS-2E contained surface water during 69%, 58%, and 73% of the observations, respectively. Relatively persistent water was found in depressions between boulders or scour holes (TS-1W and TS-1C), and in shallow bedrock depressions (TS-1E). Reaches TS-1E, TS-2W, and TS-2C contained surface water during 41%, 31%, and 17% of the observations, respectively. Although occasional small flows were recorded at gage E2015, no water was ever observed in reach TS-3.

Lower Mortandad Canyon Hydrologic Segment

Surface water is ephemeral and occurs infrequently in the lower Mortandad Canyon hydrologic segment. This canyon segment is characterized by a broad flat canyon floor with an indistinct drainage system. It contains thick alluvial deposits (up to 30 m [100 ft]) that rapidly imbibe the rare surface water flows that reach this part of the canyon.

No visual observations of surface water were ever made below the confluence with Ten Site Canyon during the 2003–2005 surveillance period. However, an exception flood event did occur in August 2006. As noted in Table 7.2-2, gage E202, which records flow entering this section of the canyon, recorded measurable flow during only about 14% of the days during its period of record (since 1997). As illustrated in Figure 7.2-4, flows are infrequent and normally very small, with the exception of occasional major flood events. When flow occurs, the water is routed through three sediment traps dug into the alluvial channel. The sediment traps dam the water into retention basins so that contaminated sediments settle, and the impounded surface water then infiltrates into the permeable alluvium. Gage E203 (Figure 7.2-1), located below the sediment traps, has never recorded flow during its period of record since 1996. Before 2005, the sediment traps were generally continuously dry since December 1997 except for a post-fire event in the upper sediment trap on May 26-29, 2001. Since then, the upper sediment trap has filled with water on August 24, 2005 and August 25, 2006. Gage E204 (Figure 7.2-1) at the Laboratory boundary with San Ildefonso Pueblo has also never recorded flow during its period of record (since 1993). Stream flow extended nearly to the Laboratory boundary for a major flood that occurred on August 25, 2006 (after the streamflow gage data for this report were compiled). Clearly, however, surface water flow in the lower Mortandad Canyon hydrologic segment is a rare event.

In the lower Mortandad Canyon Hydrologic Segment from the San Ildefonso boundary to the Rio Grande, flow is probably derived from local rainfall events and/or flow from tributaries entering Mortandad Canyon below the Laboratory boundary. Although no documented flow measurements in this reach are available, the stream channel shows evidence of at least occasional flow in places, and tributaries like Cedro Canyon have likely fed water locally into lower Mortandad Canyon. Flow is ephemeral only to the confluence of Cañada del Buey. Intermittent or perennial flow occurs from the Cañada del Buey, confluence to the Rio Grande, fed by White Rock WWTP discharges.

7.2.1.2 Alluvial Groundwater

Surface water infiltrates into the canyon bottom alluvial sediments until its downward movement is impeded by zones of lower permeability, usually weathered tuff, forming a perched alluvial aquifer with intermittently varying levels of saturation. The alluvial groundwater conceptual model is based on water-level responses to precipitation and streamflow data, and to effluent discharge. In addition, recent field observations have added to the conceptual understanding of the alluvial groundwater system, indicating that the system is complex and heterogeneous. In much of the watershed, a perched zone of saturation exists at the base of the alluvium where it overlies less permeable bedrock. Otherwise, the

alluvium above and adjacent to the perched zone is unsaturated. Figure 7.2-8 shows the extent of the alluvial groundwater based on average alluvial water levels for the summer of 2005. Figure 7.2-9 is an isopach map showing thickness variations in the alluvium from the confluence of Mortandad and Ten Site Canyons to the eastern Laboratory boundary. Figure 7.2-10 shows the distribution of geologic units beneath the alluvium in the same area.

A series of plots, shown in Appendix F, present time series of water levels at selected alluvial wells. These time series are discussed in the following sections to illustrate the relationship of alluvial water-level fluctuations to precipitation and runoff events. Historically, effluent discharges from the TA-50 RLWTF have represented a large percentage of the watershed water balance. However, they have steadily declined since 1998 to where they comprised only about 10% of the flow recorded at gage E200 in 2005 (Figure 7.2-2). Whereas historically the main volume of the alluvial groundwater body may have been fairly steady, it has gradually become more dependent on recharge from naturally occurring runoff as the influence of outfall discharges throughout the watershed has diminished. This has resulted in highly variable saturation conditions in the alluvium with notable transient responses to recharge from major runoff events.

In addition to temporal variations, the model also addresses spatial variations in the nature of the water-level record and the relation of water-level responses to precipitation and streamflow. A series of plots, shown in Appendix F, also incorporate these data to describe the system. The plots include daily precipitation measured at the TA-06 meteorological station located on Two-Mile Mesa, approximately 970 m (3180 ft) south-southwest of the headwaters of the upper Mortandad Canyon hydrologic segment, as well as mean daily discharge measured at streamflow gaging stations E200 and E202. The TA-06 precipitation record, obtained from the Laboratory meteorological database (http://weather.lanl.gov), was chosen because it is the station closest to the upper part of the watershed, which is the main source area for runoff.

The following discussion describes variations in alluvium thickness and downcanyon changes in suballuvium geology for the Mortandad watershed. Results of the alluvial water-level study are also summarized from Appendix F. The reader is referred to Appendix F for a detailed discussion of spatial and temporal variations in water-level data for the alluvial wells in each of the hydrologic segments in the watershed.

Upper Mortandad Canyon Hydrologic Segment

Alluvium is generally thin in the upper Mortandad Canyon hydrologic segment. The thickness of alluvium is about 1 m (3 ft) at MCO-0.6, located below TA-48 approximately 780 m (2560 ft) above the Effluent Canyon confluence, and 1.8 m (5.9 ft) at MCA-1, located approximately 70 m (230 ft) above the Effluent Canyon confluence (Figure 3.2-1, Plate 1). Alluvium is underlain by poorly welded to nonwelded tuffs of Tshirege unit Qbt 3 in the westernmost part of this hydrologic segment and by strongly welded tuffs of Tshirege unit Qbt 2 in the central and eastern parts of this hydrologic segment (Figure 7.0-1).

Since mid-2005, the alluvial groundwater system has typically been dry or nearly dry in the late winter, spring, and early summer seasons until recharged by summer storm runoff. The thin alluvium results in a limited ability to store groundwater. As a result, alluvial saturation levels in the upper canyon areas respond nearly instantly to recharge from runoff events, and recession of water levels is generally rapid afterwards.

Effluent Canyon Hydrologic Segment

Alluvium in the Effluent Canyon hydrologic segment is generally less than 1 to 2 m (3 to 6 ft) thick, and portions of the stream flow in a bedrock channel. Alluvium is 1.6 m (5.4 ft) thick in the wetlands at MCA-4, but the stream forms a steep-walled channel with little alluvium east of the wetlands. Alluvium is underlain by poorly welded to nonwelded tuffs of Tshirege unit Qbt 3 in the headwaters of this drainage and by strongly welded tuffs of Tshirege unit Qbt 2 in the central and eastern parts of this hydrologic segment.

Hydrograph data (Appendix F) show similar aquifer behavior to that seen in the upper Mortandad Canyon hydrologic segment. Alluvial water levels rise rapidly in response to stormwater runoff events associated with summer and fall precipitation events, and the groundwater responses occur virtually instantaneously, correlating well with the streamflow record at gaging station E200. However, alluvial saturation levels are more persistent in the Effluent Canyon hydrologic segment due to the TA-50 and TA-55 outfalls that contribute to recharge that provides a base flow saturation level of generally 0.3 to 0.6 m (1 to 2 ft).

Middle Mortandad Canyon Hydrologic Segment

Alluvium is generally thin in the western half of the middle Mortandad Canyon hydrologic segment, and it becomes progressively thicker from approximately the center of the segment to the confluence with Ten Site Canyon to the east (Figure 7.2-9). Alluvium is about 1.8 m (6 ft) thick at MCA-5 at the upper end of the segment, 8.8 m (29 ft) thick at MCB-5, and 18 m (60 ft) thick at RES-2 near the confluence with Ten Site Canyon. Because of the inaccessible terrain, there are no boreholes between MCA-5 and MCB-5 (Figure 3.2-1, Plate 1), and there is no information on the thickness of alluvium in that part of the canyon. The thin alluvium in the western half of the middle Mortandad Canyon hydrologic segment overlies strongly welded tuffs of Tshirege unit Qbt 2. The thickening alluvium in the eastern half of the middle Mortandad Canyon hydrologic segment overlies progressively older and more porous bedrock units in a downcanyon direction, including the poorly welded tuffs at the base of Qbt 2, nonwelded tuffs in Qbt 1v and Qbt 1g, and poorly consolidated sediments of the Cerro Toledo interval (Figures 7.0-1 and 7.2-8).

The alluvial groundwater in the middle Mortandad Canyon hydrologic segment is a transitional zone between the dynamically responding behavior of the upper canyon segments and a more stable and slowly responding system in the lower canyon segments. In the upper part of the middle Mortandad Canyon hydrologic segment (about 200 m [655 ft] below the Effluent Canyon confluence), a thin perched aquifer is restricted within a narrow bedrock channel and has little capacity for aquifer storage. This results in highly transient saturation conditions with instant responses to runoff recharge events followed by rapid recessions (generally a few days). Here the alluvial aquifer was dry about half the time (during the winter and spring seasons) since mid-2005.

Farther downcanyon (about 400 m [1310 ft] above the Ten Site confluence), intermittent and variable saturation levels still exist. A time lag of several weeks between a major surface runoff event and a corresponding rise in the water level indicates that alluvial groundwater recharge in this canyon segment is primarily from groundwater underflow that was recharged by infiltration of runoff further upcanyon. Only after persistent levels of alluvial saturation are maintained do flood events result in nearly instantaneous water-level rises showing the influence of rapid recharge from local infiltration.

Near the Ten Site confluence, the delayed recharge effect is more pronounced with time lags of several months between major streamflow events and alluvial groundwater recharge responses. Also, much longer recessional limbs (weeks to months) in the alluvial hydrographs from this area reflect an enlarged aquifer storage capacity attributable to the deepening package of alluvial sediments present beneath the widening canyon floor. Most water movement in the alluvial aquifer near the Ten Site confluence is

probably lateral within the alluvium, but some percolation losses from the base of the alluvium are also possible.

Ten Site Canyon Hydrologic Segment

Alluvium is relatively thin in the western half of the Ten Site Canyon hydrologic segment. This alluvium overlies poorly welded to nonwelded tuffs of Tshirege unit Qbt 3 in the headwaters of the canyon and strongly welded tuffs of Tshirege unit Qbt 2 near well R-14 (Plate 1). In the eastern part of the Ten Site Canyon hydrologic segment, as the canyon exits the hard tuffs of Tshirege unit Qbt 2, the valley floor flattens and broadens eastward, and the alluvium becomes significantly thicker. At well TSCO-6 the alluvium is 6.5 m (21.3 ft) thick, and at R-33 the alluvium is 20 m (66 ft) thick (Figure 7.2-9). Alluvium in the eastern half of the Ten Site Canyon hydrologic segment overlies progressively older bedrock units in a downcanyon direction, including the poorly welded tuffs at the base of Qbt 2, nonwelded tuffs in Qbt 1v and Qbt 1g, and poorly consolidated sediments of the Cerro Toledo interval (Figure 7.2-10).

Alluvial well TSWB-6 has been dry during every measurement event since its installation in 1994. Newly installed well TSCA-6 encountered alluvial water but the period of record is too short to evaluate the hydrograph. Therefore, no water-level data for Ten Site Canyon are summarized here.

Lower Mortandad Canyon Hydrologic Segment

Alluvium reaches its maximum thickness in the lower Mortandad Canyon hydrologic segment (Figure 7.2-9). From west to east, the thickness of alluvium varies from 21.2 m (69.5) ft at MCB-8, 25 m (82 ft) at MCB-10, 34.3 m (112.5 ft) at MCOBT-8.5, and 32.8 m (107.5 ft) at MCA-9 (Figure 3.2-1, Plate 1). From the vicinity of R-15 to the San Ildefonso Pueblo boundary, the alluvium-filled basin is asymmetric, with deeper alluvium occurring beneath the northern part of the canyon floor (Figure 7.2-9). Drill-hole data and cross-canyon resistivity profiling (see Section 7.2.1.3 and Appendix H) support the interpretation of asymmetry in the alluvial-filled basin, with gentler suballuvial slopes to the south and steeper slopes to the north. Mass-wasting apparently contributed to the alluvial fill along the steep north wall of the canyon; colluvial blocks up to 3 m (10 ft) in diameter are intercalated with fluvial sediments at MCOBT-8.5 (Broxton et al., 2002, 76006). Alluvium is underlain by Cerro Toledo fluvial deposits in the western part of the lower Mortandad Canyon hydrologic segment and by Otowi Member ash flow tuffs in the central and eastern parts (Figure 7.2-10).

In the lower Mortandad Canyon hydrologic segment, where alluvial groundwater is most prevalent, time lags of 5 to 6 months between runoff events and recharge responses in the alluvial aquifer are typical. Greater aquifer storage is available because of the thickening alluvial sediments causing long recessional limbs in alluvial hydrographs of up to 2 years. Infiltration losses from the alluvium in this canyon segment limit the extent of saturation. The downgradient extent of alluvial saturation occurs near a point about 700 m (2300 ft) below the Ten Site confluence where infiltration losses from the alluvium have led to less than fully saturated conditions spanning time periods of several years. In the easternmost wells with alluvial saturation, time lags of 8 to 17 months for response to upstream recharge events have been observed.

7.2.1.3 Vadose Zone

The vadose zone is defined as the region between the land surface and the top of the regional aquifer (see Figure 7.0-1). The vadose zone is about 365 m (1200 ft) thick beneath the upper Mortandad Canyon hydrologic segment and 245 m (800 ft) thick beneath the eastern portion of the lower Mortandad Canyon hydrologic segment. The discussion in this section will focus on the unsaturated portions of the vadose

zone. Sections 7.2.1.2 and 7.2.1.4 provide detailed descriptions of the alluvial groundwater and intermediate-perched zones, respectively, which are saturated intervals located within the vadose zone. This subsection initially focuses on the shallow vadose zone (i.e., from the land surface through the Bandelier Tuff), and then concludes by discussing the deep vadose zone (including the Cerros del Rio basalts and the Puye Formation, Figure 7.0-1). In addition, specific discussions of flux meter measurements and VECTOR in situ permeable flow sensor data collected in the Mortandad watershed are presented in Appendix M.

Volumetric Water Content

One of the most important hydrologic characteristics of the vadose zone is water content, and volumetric water content profiles for recent Mortandad boreholes are shown in Appendix B. The borehole profile data show that water contents vary widely with depth as well as up and down and laterally across the canyon. For example, in MCB-7, volumetric water contents range from less than 5% to saturation (e.g., 40%–50%) within the alluvium. Variability such as this plays an important role in the rates of water and contaminant movement in the canyon because fluxes in unsaturated media (both vertical and lateral) are strongly controlled by water content. As a demonstration of this variability, average volumetric water contents are summarized for each borehole by stratigraphic unit (and in one case by depth interval) in Table 7.2-4. Boreholes are also ordered from upcanyon (at the top of the table) to downcanyon so that along-canyon values can be compared. Note that MCB-15 is in Ten Site Canyon, and MCI-1 and MCI-10 were not drilled in the Mortandad Canyon bottom.

A cross section showing the spatial distribution volumetric water content along the axis of Mortandad Canyon is shown in Figure 7.2-11. This figure shows an interpolated representation of all available volumetric water content data collected in the Mortandad watershed as of 2005. The contours indicate that a large fraction of the vadose-zone moisture is located near and below the confluence of Mortandad Canyon and Ten Site canyons. This area is represented in Figure 7.0-1 as the zone of greatest percolation of alluvial groundwater to the deeper vadose zone, as represented by the large vertical arrows. This area coincides with zones containing persistent and intermittent alluvial groundwater and the only occurrences of intermediate-depth perched groundwater that show influences from Mortandad sources. Much of this wetter area is underlain by thick alluvium overlying the Cerro Toledo interval with locally high moisture contents (Figures 7.0-1, 7.2-9, and 7.2-10). Together, these data suggest alluvial groundwater is the source of enhanced percolation to the underlying rocks of the vadose zone. The loosely consolidated sediments of the Cerro Toledo interval may facilitate deep percolation in this area.

Alluvial groundwater is often perched at or near the contact between alluvium and underlying Cerro Toledo deposits. However, high moisture contents (as well as soluble contaminants such as perchlorate) commonly extend downward into the underlying Cerro Toledo deposits (Figure 7.2-11 and 7.2-12). Moisture and contaminant profiles indicate that the base of saturation does not represent a no-flow barrier. Rather, elevated values for moisture and soluble contaminants persist into deeper bedrock units that are not fully saturated.

Table 7.2-4 compares moisture contents for rocks of the upper vadose zone on a unit-by-unit basis. From these data, it is evident that the 0–6-m (0–20-ft) depth interval has the lowest overall water contents. Water contents at this depth are affected greatly by evapotranspiration (evaporation plus transpiration) losses, and the 0–6-m (0–20-ft) depth interval likely has the largest temporal variability, especially close to the ground surface, because of the dynamics between evapotranspiration, infiltration, and percolation. These data suggest that although the RLWTF outfall and runoff provide significant water to the canyon, evapotranspiration still plays a large role in the canyon water balance. Additional evidence for this control is described later in the discussion on stable isotope profiles.

Deep alluvium (>6 m [>20 ft]) shows a great deal of variability in volumetric water content, much of which is related to the presence or absence of alluvial saturation. There is a suggestion that water contents decrease in the deep alluvium in locations near the Laboratory boundary (i.e., MCOBT-8.5 and R-28); however, MCB-16 has a relatively high average water content of 21%.

Tshirege Member unit Qbt 2 (>6 m [>20 ft]) was observed in only two canyon bottom holes (MCB-1 and MCB-2), and average water contents vary between 10% and 24%. MCB-1 is located in Effluent Canyon above the TA-50 RLWTF outfall, and MCB-2 is located at the confluence of Mortandad and Effluent canyons (Plate 1). None of the Qbt 2 samples in these two boreholes had water contents over 25%, and both boreholes were dry when drilled. Thus, the strongly welded nature Qbt 2 and the upper canyon hydrological conditions appear to inhibit the formation of shallow perched saturated zones in this setting.

Tshirege Member unit Qbt 1 has a similar range of average water contents to Tshirege unit Qbt 2; however, Qbt 1 was observed in more boreholes. One interesting note is that a horizon of nearly saturated or saturated tuff was observed in MCB-2 near the contact of Tshirege subunits Qbt 1v and Qbt 1g. Similar occurrences of enhanced moisture at the Qbt 1v/Qbt 1g contact have been observed in other parts of the Laboratory (e.g., borehole 49-2-700-1 at TA-49, Stimac et al., 2002, p.7).

The Cerro Toledo interval has some of the highest average water contents presented in Table 7.2-4. Some of these water contents may be high because of leakage from the alluvial perched horizons during drilling. However, the number of observed high values indicates that the Qct is one of the wetter units within the canyon.

The Otowi Member average water contents tend to center around the high teens to low twenties, indicating that the Otowi is 30%–40% saturated (assuming 45% porosity) from R-1 to near the Laboratory boundary. However, the specific water-content profiles for boreholes MCB-14, MCOI-6, MCOI-8, R-1 and R-15 (Appendix B) show extensive intervals with water contents approaching thirty. These wells are located in an area with persistent alluvial groundwater and are shown in Figure 7.0-1 as being located in the region of enhanced vadose-zone flow.

In contrast to the upper vadose zone described above, there is much less information available about the deeper vadose zone (e.g., the Cerros del Rio basalts and the Puye Formation). Only one hole was cored within the deep zone, and no core data exist for the Puye Formation in Mortandad Canyon. At R-15, volumetric water contents in the basalt are less than 10% from about 150 to 215 m (500 to 700 ft) (Longmire et al. 2001, 70103). Below the intermediate perched zone, water contents increase to about 30% near the contact with the Puye Formation. The basalt units are difficult to characterize because they can have a wide range of porosities and hydraulic conductivities, depending on whether the basalts are massive or fractured, or if interflow/paleosol zones are present. Fracture porosity is a possible route for fast transport through the basalts. The closest proxies for the deep vadose zone in Mortandad Canyon are R-12 and R-9 in Sandia and Los Alamos canyons, respectively. R-12 and R-9 water contents in the Cerros del Rio basalts are generally similar to the 150 to 215 m (500–700 ft) zone at R-15 (i.e., <10%; Broxton et al., 2001a, 2001b). However, R-12 water contents increase to over 20% in interflow zones at basalt subunit contacts. At R-12 and R-9, water contents are also around 10% in the clay-poor sedimentary deposits in the upper part of the Puye Formation. In the lower Puye Formation (near the regional aquifer), water contents increase to 30%–40% in clay-rich sedimentary deposits. The Puye deposits beneath Mortandad Canyon are most similar to the clay-poor deposits in the upper Puye Formation at R-9 and R-12.

The water contents in rocks beneath Mortandad and Ten Site canyons (i.e., MCB-15) are generally higher than is observed beneath mesa locations on the Pajarito Plateau. For example, MCI-10, a mesa borehole adjacent to Mortandad Canyon, has the lowest water contents observed in this investigation for Tshirege

unit Qbt 1 and the Otowi Member (Table 7.2-4). Thus, higher fluxes are expected to be confined to those areas beneath Mortandad Canyon and are not expected to extend beneath the adjacent mesas. These results are consistent with observations made in other areas of the Laboratory, which show that canyons are often wetter than mesa locations (Birdsell et al., 2005, 92048; Newman 1996, 59118)

Oxygen and Hydrogen Stable Isotope Profiles

Pore water oxygen ($\delta^{18}O$) and hydrogen (δD) stable isotopes are another set of data that provide insights on vadose zone processes within Mortandad Canyon. These data were described previously by Longmire et al. (2001, 70103) and Broxton et al. (2002, 76006). They are useful in vadose zone studies because they are sensitive indicators of processes such as evaporation and mixing. Stable isotope profiles were collected from core samples from R-15, MCOBT-4.4, and MCOBT-8.5; $\delta^{18}O$ depth profiles are shown in Figure 7.2-13. The figures show two key features. The first feature is that all three holes show a zone in the shallow alluvium (Qal) where pore waters are isotopically heavy (less negative). For example, R-15 has a $\delta^{18}O$ of –5 ‰ in the shallow alluvium, and the MCOBT holes have values in the –7 to –8 ‰ range. As discussed by Broxton et al. (2002, 76006), such values are characteristic of waters that have undergone evaporation. Mortandad Canyon alluvial well samples collected in 1999 and 2005 range from –6 to -12 ‰. Some of the heavier values may be related to evaporated waters that are generated during water treatment and are subsequently released through outfalls to the canyon. However, the heavier alluvial aquifer values are also consistent with the low water contents observed in the shallow tuffs and alluvium (e.g., <6 m [<20 ft] in Table 7.2-4). Thus, it is likely that evaporative losses within the canyon are an important part of the canyon water budget. Although the stable isotopes are not sensitive to transpiration, the substantial amount of vegetation (including ponderosa pines) in the canyon indicates that there is also large water loss through transpiration. Thus, evapotranspiration (evaporation plus transpiration) must play a significant role in the canyon water budget despite the additions of water from runoff and five operating outfalls.

The second feature in the isotope profiles (Figure 7.2-13) is the shift from isotopically heavy values near the surface to relatively constant but significantly lighter values with depth. The reduction of variation in isotope values (with a few exceptions) occurs within the Qct and Qbo, and values are similar to the average annual precipitation values for the plateau (–10 to –11 ‰). Seasonal- and precipitation event-based variations in the isotopic composition of water inputs to the canyon are substantial based on the Mortandad alluvial data discussed above and on other studies on the plateau (e.g., LANL 1998, 59891; Newman et al. 1998, 76883). Thus, the shallow parts of the Mortandad Canyon profiles likely reflect some of this variation. In addition, isotope values at and below the base of the alluvium may contain alluvial groundwater from an upcanyon effluent source that flowed laterally to the particular location. After about 15 m (50 ft), much of the variation is dampened out. This reduction of variability in the deeper parts of the profiles indicates that substantial mixing occurs as water from different sources (i.e., effluent, runoff and evaporated precipitation, all from different time periods) moves through the upper vadose zone. Mixing is an important aspect of the canyon hydrology because it means that variations in contaminant inputs over time will be substantially smoothed out as well.

Surface DC Resistivity Survey

Surface DC resistivity surveys of the Mortandad watershed were conducted in 2002 and 2003 (Geophex,Ltd., 2003, 84540, Appendix B) and are summarized in Appendix H. This technique allows for noninvasive interrogation of large portions of the subsurface and can potentially identify conductive zones that may be related to moisture distribution (see Section 3.2). Figure 7.2-14 shows the survey results for the line run in the narrow section of the middle Mortandad Canyon hydrologic segment, from the

confluence with Effluent Canyon to just past well MCB-5. The survey results are compared with gravimetric moisture and perchlorate concentration profiles with depth at three wells.

In Effluent Canyon downcanyon of the TA-50 RLWTF outfall, thin alluvium overlies strongly welded tuff that forms an impermeable barrier to infiltration. The surface DC resistivity profile down the axis of the canyon (Geophex Ltd., 2003, 84540) indicated that the rocks beneath the channel are highly resistive (perhaps drier) below depths of a few feet.

In the western portion of the middle Mortandad Canyon hydrologic segment, between MCA-5 and MCB-5, resistivity profiling (Geophex 2003, 84540) indicates deepening of an upper conductive horizon as the stream channel progressively cuts down section through bedrock tuffs that are strongly welded (middle of Tshirege unit Qbt 2) into the poorly welded tuffs at the base of Tshirege unit Qbt 2 and in Tshirege unit Qbt 1v (Figure 7.2-14). The resistivity data suggest that infiltration is restricted to relatively shallow depths in the western portion of the middle Mortandad Canyon hydrologic segment. Nevertheless, core moisture profiles at MCOI-1, drilled along the Qbt 2 bench within the canyon, show that moisture can accumulate along deeper small scale features such as the Tshirege Qbt 1v/Qbt 1g contact, albeit with no evidence of associated contamination (Figure 7.2-14).

In the lower part of the Ten Site Canyon hydrologic segment, the surface DC resistivity profile down the axis of the lower canyon (Geophex 2004, 84540; see Appendix H) indicates that the rocks beneath the channel are moderately conductive at depths of 15 to 30 m (50 to 100 ft).

The eastern part of the middle Mortandad Canyon hydrologic segment and the western part of the lower Mortandad Canyon hydrologic segment from R-1 to approximately the location of MCOBT-8.5 include the most abundant and widespread shallow conductive intervals in electrical profiling (resistivity <100 ohm-m). Much of this conductive structure is beneath alluvium and within the Cerro Toledo deposits (see Appendix H). In this section of the canyon, the axial alluvial deposits thicken from about 10 to 33 m (30 to 110 ft). The contact between base of alluvium and the Cerro Toledo deposits is irregular, indicating branching channels cut into the top of the Cerro Toledo interval. Stratigraphy within the Cerro Toledo interval is complex and may lead to locally variable hydrogeologic properties at the base of alluvium (see Appendix G for discussion of heterogeneity in alluvium/colluvium and the Cerro Toledo interval).

7.2.1.4 Intermediate-Perched Zones in Mortandad Canyon

This section describes the physical setting of intermediate-depth perched groundwater in Mortandad Canyon. These perched groundwater bodies represent local areas of saturation in the deeper parts of the vadose zone and are too small for use as municipal water supplies. Nonetheless, they are of interest because (1) their chemical and isotopic characteristics help constrain groundwater transport rates through the vadose zone; (2) perching horizons may facilitate, divert, slow, or stop vertical migration of groundwater through the vadose zone, or they may indicate the presence of a fast subsurface pathway, depending on their hydraulic characteristics; and (3) they can be used as vadose-zone monitoring points that provide early warning of contaminants approaching the regional aquifer. The following descriptions of intermediate perched zones in Mortandad Canyon are modified from the recent paper by Robinson et al. (2005, 91682). Additional discussion about the constraints on saturated thickness and lateral extent of these perched zones relevant to Mortandad Canyon is provided in Appendix J.

Two groups of wells encounter perched water within the Cerros del Rio basalts beneath Mortandad Canyon. In one set of wells, MCOBT-4.4 and MCOI-4 near the Ten Site Canyon confluence, a thin perched zone occurs at a depth of about 160 m (520 ft), within the clay-rich basaltic rubble at the top of the Cerros del Rio basalts (Figure 7.0-1). The saturated thickness of this zone is approximately 1 m (3 ft). The mean water elevation is 1925.0 m (6315.7 ft) for MCOBT-4.4 and 1925.0 m (6317.1 ft) for MCOI-4.

Appendix J provides a discussion of temporal water-level fluctuations in the two wells. The apparent perching horizon at this location is a massive lava flow with few fractures. The massive lava causes perching because it lacks sufficient permeability at the existing level of saturation to drain the influx of new water. Fractures within the massive perching lava apparently do not conduct substantial groundwater flux. The inability of fractures to drain the perched zone is probably due to a combination of factors including the sealing of fractures by clay minerals and/or the limited number of fractures along the flow paths (flux along the fractures is smaller than the infiltration rate feeding the perched zone). Contaminant concentrations in groundwater in both wells vary over time (see Sections 7.2.2 and 7.2.3.), indicating water in the perched zone is flowing along a hydraulic gradient (i.e., not static).

About 350 m (1150 ft) downcanyon, a second group of wells, including MCOI-5, MCOI-6, and R-15, encountered perched water in the lower part of the Cerros del Rio basalt (Figure 7.0-1). The depth to water is 210 m (689 ft) at MCOI-5 and 202 m (664 ft) at MCOI-6. At R-15, the depth to water is poorly constrained by data collected during the drilling program, but it probably occurs between 197 m (646 ft) and 222 m (729 ft) (see Appendix J for more discussion of R-15 water-level data). The equivalent water elevations are 1869 m (6130.4 ft) at MCOI-5, 1874 m (6147.1 ft) at MCOI-6, and between 1857 and 1882 m (6091 and 6173.6 ft) at R-15. Minimum saturated thicknesses are 16.8 m (55 ft) at MCOI-5 and 21.9 m (72 ft) at MCOI-6; at R-15 estimates of saturated thickness range between 4.9 m (16 ft) and 30 m (99 ft). The perched water occurs in a combination of fractured and porous media. The fractured media consist of dense, massive lava flows cut by high-angle cooling fractures. These fractured lava flows are separated by nearly horizontal beds of porous interflow breccias. The variable static water levels and differences in saturated thicknesses within these closely spaced wells may be caused by the heterogeneous nature of perched groundwater systems located within basaltic rocks. This heterogeneity can reflect poor hydrologic communication among fractures, partial drainage of poorly connected perched zones during drilling, or spatial and temporal variability in the infiltration rate feeding the perched zone at the time of drilling. At R-15, the perching horizon appears to be clay-rich, flow-base rubble or underlying silty basaltic sands. The perched zones at MCOI-5 and MCOI-6 were probably not fully penetrated during drilling, and the perching horizons in these boreholes are uncertain.

Because of their different geologic settings, the perched groundwater occurrences at MCOBT-4.4/MCOI-4 and R-15/MCOI-5/MCOI-6 probably represent two unrelated groundwater bodies of limited lateral extent along the canyon axis (Figures 7.0-1 and 7.2-11). Based on the distribution of water-bearing vs. dry boreholes, the lateral extent of these perched groundwater bodies is probably less than 450 m (1500 ft).

A potential intermediate perched water zone was noted while drilling well MCOI-8, located about 325 m (1100 ft) upcanyon of the Ten Site Canyon confluence. A well was installed in the lower Cerros del Rio basalt where saturation was considered most likely based on borehole water-level measurements, video logs, and induction logs. Water-level measurements made since well installation indicate that water is present in the well sump but not in the screen. At the time of this report it is uncertain whether intermediate-perched groundwater is present at MCOI-8. A continuous-record water-level transducer is installed, and water levels are being monitored.

Other potential intermediate-perched water zones were also noted in the well completion report for boreholes MCRES-4 and MCB-7 (Kleinfelder 2006, 92486; Appendix B). At MCRES-4, possible perched water was noted in the lower Tshirege Member (Qbt 1g) between 21.3 and 22.9 m (70 and 75 ft). At MCB-7, the completion report indicates perched water occurred in the lower Tshirege Member (Qbt 1g) between 21 and 22.6 m (69 and 74 ft) and in the Cerro Toledo interval between 25.6 and 27.1 m (84 and 89 ft). Both boreholes encountered alluvial groundwater systems and there were problems sealing off the alluvial water from the deeper parts of the boreholes. Because of these problems, the intermediate-

perched groundwater at MCRES-4 and MCB-7 are considered possible, but poorly constrained, occurrences.

Figure 7.0-1 shows deep perched water within the lower Cerros del Rio lavas based on evidence from drill holes R-12 and R-10/10A, which are located in lower Sandia Canyon near the Laboratory boundary. There are no wells in this part of Mortandad Canyon, and it is not known whether these perched waters extend beneath the eastern part of the Mortandad watershed. Sources of the deep perched water observed at R-12 and R-10/10A are poorly constrained, but water-quality data indicate that these groundwaters do not contain contaminants associated with the Mortandad hydrologic system.

Water-level fluctuations in some of the perched intermediate zones were observed in 2005 following large rainstorms. These were originally hypothesized as rapid flow from the surface to the intermediate locations. However, the water-level fluctuations are probably not caused by infiltration of surface water during flood events but are a result of barometric pressure effects, as discussed in Appendix L.

7.2.1.5 Regional Aquifer Model

The water table of the regional aquifer, which lies approximately 300 m (1000 ft) below the canyon floor in Mortandad Canyon occurs within Miocene pumiceous sedimentary deposits that underlie the Pliocene Puye Formation. At a larger scale, the regional aquifer comprises several sedimentary and volcanic hydrostratigraphic units of varying thickness, lateral extent, and permeability. The hydraulic conductivity of aquifer rocks is highly heterogeneous and averages approximately 1 m/d (3 ft/d) at a regional scale. The regional aquifer is a complex hydrogeological structure that includes confined and unconfined zones that are characterized by a spatially varying degree of hydraulic communication.

The shallow portion of the regional aquifer near the water table is predominantly under phreatic (unconfined) conditions. The phreatic zone is mainly encountered in the Puye Formation and the underlying pumiceous sedimentary deposits and has limited thickness (approximately 30 to 50 m [100 to 165 ft]). The groundwater flow and transport in this zone are believed to generally follow the shape of the regional water table. The flow directions are then east-southeast, toward the Rio Grande. The hydraulic gradient along the regional water table is relatively steep; on the order of 0.01. The shape of the regional water table (i.e., the flow directions in the phreatic zone) is predominantly controlled by the existing areas of regional recharge (the Jemez Mountains with some contributions on the Pajarito Plateau) and discharge (springs in White Rock Canyon and the Rio Grande). The impact of Pajarito Plateau water-supply pumping on the flow directions in the phreatic zone is negligible (Appendix O).

The deep portion of the regional aquifer is predominantly under confined conditions. Water-supply pumping is performed predominantly in the deep portion of the regional aquifer. The pumping has negligible impact on the flow directions in the phreatic zone above beneath the Mortandad watershed because of poor hydraulic communication (Appendix O). The boundary between the shallow phreatic and the deep confined zones is not well defined. The hydraulic separation is caused by stacking highly stratified, gently dipping sedimentary deposits made up of individual beds characterized by highly variable hydraulic permeabilities and varying spatial extents. These strata are encountered in the Puye Formation and Santa Fe Group (Figure 7.0-1). Therefore, the boundary between the shallow phreatic and the deep confined zones is not a well-defined aquitard but instead represents the net effect of stacked beds with variable hydraulic properties, resulting in a vertical permeability that is at least 3 orders of magnitude lower than the horizontal permeability parallel to the bedding. For all the practical purposes, this causes a dominant hydraulic separation between the shallow phreatic and the deep confined aquifer zones that can be considered to be equivalent to an “aquitard.” However, the poor hydraulic communication does not necessarily preclude the possibility for contaminants to migrate through the “aquitard.”. Because of

pumping in the deep aquifer, there is a substantial vertical component of the hydraulic gradient between the shallow phreatic and the deep confined zones. This creates the possibility for groundwater flow and contaminant migration through the aquitard along hydraulic windows by shortcutting between the layering.

A regional representation of the water-table elevation is shown Figure 7.2-15. Similar spatial analysis of the hydraulic pressures in the deep portion of the regional aquifer is not feasible because of limited data.

Appendix N provides a spatial analysis of water-table variability and discusses the assumptions implemented in the generation of a regional water-table map (Figure 7.2-15). Appendix O provides analysis of temporal variability of water-table elevations measured at the monitoring boreholes near Mortandad Canyon (R-1, R-11, R-13, R-15, and R-28). Appendix P discusses the available information for the pumping-rate variability at the water-supply wells. These appendixes provide more detailed analyses of the potential impact of water-supply pumping on the groundwater flow and transport directions in the shallow phreatic zone of the regional aquifer. More details about this conceptual model of groundwater flow and transport beneath the Pajarito Plateau can be found in (Vesselinov 2005, 89753; Vesselinov 2005, 90040; Vesselinov 2004, 90117).

7.2.2 Contaminant Transport

Contaminant transport in the Mortandad watershed generally occurs along the pathways depicted in Figure 7.0-1. Adsorbing contaminants adhere to sediment to become part of the sediment load, as described in Section 7.1, and either stay relatively close to the release location or are transported down the canyon with surface flow events. Nonadsorbing species travel with water and follow the same flow paths that water takes. Weakly adsorbing constituents may travel with sediments or with water but generally migrate more slowly than nonadsorbing species. Strongly adsorbing species may travel with sediment or adsorb onto immobile rock surfaces. Therefore, adsorptive contaminants tend to exhibit retarded migration in the environment, and the nonadsorbing species are those that are detected in vadose-zone porewater and deeper groundwater zones.

The sections of this report that follow describe the nature and extent of COPCs in water. For each COPC, its current distribution in water is described and time histories are presented to illustrate the evolution of the COPC in the environment. The following format is used to describe these distributions.

- For surface water and alluvial groundwater, box plots showing recent (2000 to 2005) concentration data at different locations are used to define current COPC distributions throughout the watershed. Then time series plots give longer records in these waters to show concentration responses to long-term changes in effluent concentrations from the TA-50 RLWTF. In addition, shorter time series from 2000 to 2005 are presented to describe more recent concentration responses to treatment-plant enhancements and to flood events.
- For the vadose zone, contaminant distributions are described based on vadose-zone pore-water concentrations or contaminant masses as estimated from core samples. Time series concentrations are available for some perched-intermediate zones, and contaminant trends for these groundwaters are discussed.
- For the regional aquifer, time series plots present trends in concentration data for those few mobile contaminants that are observed in that zone.

A full series of plots in Appendix D provides a comprehensive overview of the spatial and temporal trends of COPCs in the Mortandad watershed. The discussion and supporting plots below provides additional information on the spatial and temporal distributions of these contaminants in key areas of the watershed.

- Box plots show concentration data between 2000 and 2005 for surface water and alluvial groundwater at sampling locations from west to east in relation to distance from the Rio Grande. These plots are useful for describing the present-day spatial distribution of COPCs and are also useful for identifying both the historical source(s) of each contaminant and the present-day "secondary" source areas. Three watershed segments are plotted. (1) The Effluent and Mortandad Canyons segment covers locations from the head of Effluent Canyon to the Mortandad Canyon confluence and then follows Mortandad Canyon eastward to the Rio Grande. (2) The Mortandad Canyon segment covers locations from the head of Mortandad Canyon to the confluence with Effluent Canyon and eastward to reach M-2E (Plate 1). (3) The Ten Site Canyon segment covers locations from the head of Ten Site Canyon to the confluence with Mortandad Canyon at well MCA-2. The sampling locations included in the plots were selected to bound known or suspected contaminant sources and generally include locations that have enough data to show variability in contaminant concentrations. The upper and lower ends of the boxes are the 75th and 25th percentiles of the data distribution, and upper and lower lines outside the boxes indicate 90th and 10th percentiles, respectively. Nondetect values are included in the plots. The paired numbers below each box indicate the number of detects (left) and nondetects (right) at each location. Detected values are represented in the plots with filled symbols, and the nondetect values are open symbols.
- Time series plots show available concentration data for surface water station E200 (and its nearby precursor GS-1) and many alluvial wells throughout the watershed for their full periods of record, which covers over a 40-yr period at many locations. Time series plots are also presented for regional wells and perched intermediate wells. Although these records are quite short, some apparent trends can be observed.
- Contaminant depth profiles show concentration as a function of corehole depth for porewater and solid-phase core. Samples for these analyses were collected when the boreholes were drilled and subsequently analyzed.

Overall, the spatial distributions of inorganic chemical and radionuclide concentrations indicate only a few key sources of the COPCs observed in groundwater and vadose-zone pore water, as described in Section 2.1. The most important source is the outfall from the TA-50 RLWTF into Effluent Canyon. Other sources include the former TA-35 WWTP outfall in Ten Site Canyon, possible discharges from cooling towers and radiochemistry laboratories at TA-48 in Effluent Canyon west of the TA-50 outfall (Plate 1) and in Mortandad Canyon west of gage E200, and sources at TA-03 with releases into upper Mortandad Canyon above the Effluent confluence. The cooling towers for the TA-03 power plant in the Sandia watershed may also have been a potential source of contaminants, especially chromium, to the groundwater beneath Mortandad Canyon.

Monitoring wells in the regional aquifer consist of both single- and multi-screen construction. Groundwater chemistry data from the single-screen completions are representative of predrilling conditions. However, two multi-screen wells do not provide fully representative data for the groundwater, especially for certain constituents subject to dissolution and desorption resulting from the affects of reducing conditions (e.g., chromium iron, perchlorate, and nitrate). The two affected wells/screens are R-14, screen 2 and R-33, screen 2.

7.2.2.1 Inorganic Chemicals in Water

Several inorganic chemicals are identified in Section 6 as being COPCs in water. Subsections below present a discussion of the spatial distribution and conceptual model for these COPCs.

Nitrate and perchlorate are the most mobile of the inorganic chemicals historically released in the watershed. Nitrate and perchlorate concentrations have been measured in surface water, and in alluvial, perched-intermediate and regional groundwaters. Their presence has also been observed in vadose-zone pore water collected from core samples from several boreholes drilled in and around Mortandad Canyon (Plate 1) since 1998. These combined results provide a comprehensive picture of subsurface contaminant distributions and migration at various locations in the watershed. In light of these results, this subsection first discusses contaminant nature and extent characteristics specific to nitrate and perchlorate within the watershed. The distributions of these nonadsorbing contaminants yield key information about subsurface pathways. The nitrate and perchlorate results in particular are useful because of the high mobility of these contaminants in the subsurface (i.e., they move at similar rates to subsurface pore water). Thus, their distribution is likely to bound the subsurface extent of other nonadsorbing contaminants that have followed the same migration pathway.

Nitrate

Nitrate is detected in surface water, alluvial and perched-intermediate groundwater, and the regional aquifer beneath Mortandad Canyon. There are both natural and anthropogenic sources of nitrate within the watershed, with Laboratory-derived nitrate produced from the dissociation of nitric acid that is neutralized before discharge. The other Laboratory source of nitrate is from treated sewage effluent in which nitrate concentrations are typically less than 5 mg/L due to denitrification taking place before discharge. Natural nitrate is common on the Pajarito Plateau and in the American Southwest (Walvoord et al., 2003, 93787). Thus, detectible levels of nitrate do not necessarily mean that contamination is present. However, it is clear that for many locations in the Mortandad watershed, the nitrate concentrations are elevated and related to historical Laboratory releases. Under oxidizing conditions, nitrate is mobile as an anion in groundwater and does not significantly adsorb onto clay minerals, ferric (oxy)hydroxide, solid organic matter, and other naturally occurring adsorbents. In the presence of denitrifying bacteria and reactive solid and dissolved organic carbon, nitrate becomes reduced to nitrogen gas. Other types of nitrate-reducing bacteria are capable of reducing nitrate to ammonium under oxygen-depleted conditions. In the discussion that follows, nitrate concentrations are based on different sampling and analysis techniques to obtain the largest data sets. Results for nitrate and nitrate plus nitrite are combined because nitrite is generally a very small part of the measured concentration. Filtered and nonfiltered results are also combined because filtration has little to no effect on nitrate concentration. Nitrate concentrations in the discussions that follows are reported in the units “Nitrate (as N, mg/L),” unless otherwise noted.

Nitrate in Surface Water and Alluvial Groundwater

Nitrate transport within the surface water and alluvial groundwater is controlled by the flow paths in these systems, which spread the contaminant laterally down the canyon, as described in Sections 7.2.1.1 and 7.2.1.2. The spatial trends in recent (2000–2005) nitrate concentrations in surface water and alluvial groundwater are shown in the box plots of Figures 7.2-16(a-c). In upper Mortandad Canyon (Figure 7.2-16[a]), in upper Effluent Canyon (Figure 7.2-16(b) above the TA-50 outfall, and in Ten Site Canyon (Fig. 7.2-16[c]), the nitrate concentrations are low (<1 mg/L), indicating that there are no recent sources contributing to the nitrate mass already in those canyon segments. However, nitrate concentrations increase in Effluent Canyon (Figure 7.2-16[b]) below the TA-50 RLWTF outfall and in

Mortandad Canyon below the confluence with Effluent Canyon (Figure 7.2-16[a]), indicating that the TA-50 RLWTF outfall continues to be the primary source of nitrate to the watershed.

Figure 7.2-17 is a time series plot covering the period 1960 through 2005. It shows the annual nitrate concentration in TA-50 effluent and the resulting concentrations at alluvial wells MCO-3, MCO-5, MCO-6, MCO-7 and MCO-7.5. The outfall nitrate concentrations averaged over 200 mg/L from 1981 to 1995, with maximum concentration approaching 500 mg/L. During this same period, nitrate concentrations in the alluvial wells were elevated with many measurements over 100 mg/L (as N). After 1995, outfall concentrations dropped below 100 mg/L, and from 2000 to 2004, the average outfall concentration was less than 3 mg/L due to improvements in wastewater treatment at the TA-50 RLWTF and concurrent source reduction implemented at Laboratory facilities that have their wastewater treated at the RLWTF. Correspondingly, concentrations in the alluvial wells have declined.

Nitrate concentrations increase spatially from west to east in Mortandad Canyon below the Effluent Canyon confluence from well MCO-5 to approximately well MCO-7.5. The trend is indicative of a dilution lag in the alluvial aquifer from west to east since improved nitrate removal began at the RLWTF in late 1999 (Section 2.1.1). The lag is due, in part, to distance from the outfall, but the increasing alluvial storage from west to east (Section 7.2.1.2) is probably a more important factor. To illustrate this, Figure 7.2-18 is a time series plot analogous to Figure 7.2-17, but it covers the period of low nitrate effluent concentrations, 2000 through 2004–2005. At well pair MCO-3/MCA-5 (Plate 1), which is located in the westernmost portion of the middle Mortandad Canyon hydrologic segment and has little alluvial storage, the concentration decline occurs almost immediately in 2000 following the drop in effluent concentration. At wells MCO-5 and MCO-6, near the eastern end of the middle Mortandad Canyon hydrologic segment, where the canyon is still narrow but the alluvium starts to thicken, the decline is delayed slightly with the greatest change in 2000 and 2001. Finally, nitrate concentrations at wells MCO-7 and MCO-7.5 have declined slowly since 2000. These wells are located in the lower Mortandad Canyon hydrologic segment where the highest amount of alluvial storage occurs. Nitrate concentrations at these distal locations should continue to decline in response to lower treated effluent concentrations and to periodic high runoff events. With few exceptions, the recent surface water and alluvial groundwater nitrate concentrations are less than the EPA Region 6 tap water MCL of 10 mg/L (Figure 7.2-17 and Figures 7.2-16[a–c]). In alluvial groundwater, these exceptions are two values at well MCO-7 (12.5 and 10.9 mg/L in February 2000 and August 2001, respectively) and one value at well MCO-7.5 (18 mg/L in 2000).

Nitrate in Vadose-Zone Pore Water and Perched-Intermediate Groundwater

Nitrate has migrated from the surface water and alluvial groundwater into the deeper vadose-zone, probably since effluent releases began in the watershed at TA-35 in 1951. Depth profiles of pore-water nitrate concentrations reflect the combined releases to the watershed (Appendix D, Figures D-2.3-1 through D-2.3-21). Nitrate was detected in every core hole analyzed in the watershed, and vadose-zone pore-water concentrations sometimes exceed 100 mg/L. The historic concentrations of nitrate in the alluvial groundwater (from 1960, these are shown in Figure 7.2-17) became the nitrate source for the deeper vadose zone in areas where perched-alluvial groundwater was present.

Figure 7.2-19 depicts the vadose-zone nitrate concentration along a longitudinal cross section through Mortandad Canyon. The figure shows nitrate concentrations measured from pore water and groundwater collected from representative characterization boreholes and regional and perched intermediate wells in the watershed. These data are also spatially interpolated using a minimum-tension technique (as implemented in the earthVision software, see Appendix I) to evaluate a generalized distribution of the concentrations between boreholes and wells, which can be used to describe characteristics about nature and extent of nitrate and migration pathways beneath the canyon.

Figure 7.2-20 depicts the distribution of nitrate mass along a longitudinal cross section through Mortandad Canyon. This mass distribution is estimated by multiplying the pore water and groundwater nitrate concentrations (Figure 7.2-19) and volumetric water content (Figure 7.2-11). Approximately 198,000 kg of nitrate has been reported as being released through the TA-50 RLWTF outfall into the Mortandad watershed from 1963 to 2005 (see Table 2.1-1). The distribution of mass, as estimated using the earthVision model (Figure 7.2-20, Appendix I), was used to estimate the current nitrate mass as it now exists distributed within and beneath the canyon, including nitrate in the alluvial groundwater, the unsaturated pore water (including alluvium), and the perched-intermediate zones. The estimated mass is approximately 228,000 kg nitrate (as N). Table 7.2-5 shows the mass distribution by strata. The estimated mass using in situ concentrations is 15% higher than the estimate made from outfall records (which also contains some inherent uncertainty), showing that the model technique provides a reasonable method for estimating in situ mass. Nearly the entire mass (99.7%) is estimated to be in the vadose-zone pore water within and stratigraphically above the Otowi member (Qbo). Only 0.1% and 0.2% of the nitrate mass are estimated to be in the alluvial groundwater and perched intermediate groundwater, respectively.

In terms of vertical extent, there is a region of elevated nitrate concentrations and mass located in approximately the upper 90 m (300 ft) of the vadose zone that extends into the mid- to lower-Otowi Member, as described above. In particular, nitrate has migrated into the Otowi Member at locations between about MCB-5 and MCOBT-8.5 (Figure 7.2-19). This is also the zone where the Otowi Member has elevated water content (Section 7.2.1, Figure 7.2-11 and Appendix B), alluvial groundwater is persistent to intermittent, perched-intermediate groundwater is observed, and apparent greater vadose-zone fluxes (Appendix M) are present. The broad zone of fairly well-defined contaminant extent is consistent with the general conceptual model of transport depicted in Figure 7.0-1.

The vertical migration of nitrate in the vadose zone west of MCB-5 is poorly constrained because of the inaccessibility of drill rigs to this part of Mortandad Canyon. However, the presence of thin alluvium over less permeable bedrock units 500 to 1000 m (1640 to 3280 ft) west of MCB-5 probably limits infiltration in that portion of the canyon. Borehole MCB-1 (Plate 1), located in Effluent Canyon above the TA-50 outfall, has very little nitrate (maximum pore-water concentration less than 1 mg/L, Figure D-2.3-1), reflecting the lack of a nitrate source and/or no migration pathway. At MCB-2, located east of the RLWTF outfall near the Mortandad Canyon confluence, observed pore-water nitrate concentrations remain low (less than 21 mg/L, Figure D-2.3-2) despite the presence of a nitrate source. Transport at this location is considered to be dominated by lateral surface water flow resulting in very little infiltration and vadose-zone transport. There is a marked change near the eastern end of the middle Mortandad Canyon hydrologic segment, where the canyon begins to widen and alluvium thickens around borehole MCB-5. From MCB-5 and further downcanyon to about MCOBT-8.5, elevated concentrations and vadose-zone mass are observed as described above.

The zone of low nitrate concentration and mass between MCOBT-8.5 and R-28 in Figures 7.2-19 and 7.2-20 is of interest. This zone likely contains a greater mass of nitrate than shown in the figures. Nitrate was detected within this zone in core holes MC-1 and MC-2, which were drilled as characterization boreholes for the proposed Advanced Hydrotest Facility (AHF). However, because of sample preservation problems (described in Appendix M), the nitrate pore-water concentrations are not accurate and were not used to generate the visualized nitrate distributions. Thus, the zone of elevated nitrate may extend east of MCOBT-8.5 toward R-28, at least down to the top of the Otowi Member, which was the maximum depth of the MC boreholes.

From R-28 east to MCB-16, near the Laboratory boundary, the frequency of high nitrate concentrations (above 100 mg/L) is substantially lower, especially when compared with the area between R-1 and MCBT-8.5. At R-28, there was only one nitrate detection above 100 mg/L. Pore-water concentrations of

nitrate are also low at MCB-16, except for three detections above 100 mg/L in an approximately 30-ft interval in the unsaturated alluvium (Figure D-2.3-13).

In order to bound the migration rates that have led to the current distribution of the main nitrate mass observed in the Mortandad watershed, several studies have estimated transport velocities based on vadose-zone chemical distributions. Estimates of vertical transport velocities of nitrate, based on a release of unique isotopically light nitrogen from October 1986 to September 1989, range between 2.5 and 2.9 m/yr (8.2 and 9.5 ft/yr) for wells MCOBT-4.4 and MCOBT-8.5, respectively (Broxton et al. 2002, 76006). Estimates of transport rates based on peak tritium releases to the canyon suggest that vertical transport rates have declined substantially from a possible maximum of 11 m/y (36.1 ft/y) in the late 1970s to about 1.36 m/yr (4.46 ft/yr) in 1999 (Kwicklis et al 2005, 90069). Finally, calibration to nitrate profiles in R-15 and MCOBT-8.5 yield approximate transport velocities of 6 m/y (20 ft/yr) in 1968 to 1.2 m/y (4 ft/yr) in 2002 (Birdsell et al. 2005, 92048). These studies apply to nonadsorbing constituents, such as nitrate, perchlorate and tritium, and indicate that vadose-zone transport velocities were greater in the past and over time have declined in response to declining outfall volumes.

Elevated nitrate concentrations are observed in perched-intermediate zones located beneath Mortandad Canyon. The presence of deep contamination indicates that there are some preferential pathways through the vadose zone that have transported comparatively small masses of nitrate to depths below the Otowi Member and beyond the main mass of the nitrate contamination. Nitrate concentrations have increased slightly from 13.2 to 16.2 mg/L in filtered samples within the perched-intermediate zone at well MCOBT-4.4 from 2002 to 2005 (Figure 7.2-21). This may indicate advancing nitrate-contaminated vadose-zone waters. Nitrate is also observed in perched-intermediate groundwaters at wells MCOI-4, MCOI-5, and MCOI-6 where reported nitrate concentrations for filtered samples over two sampling rounds in 2005 were 13 and 14.2 mg/L, 3.07 and 4.22 mg/L, and 13.7 and 16.8 mg/L, respectively (Figures D-2.2-16[f], D-2.2-17[f], D-2.2-18[f]).

In Ten Site Canyon, pore-water nitrate concentrations from the core collected at R-14 (Figure D-2.3-19), at the head of the canyon, and MCB-15 (Figure D-2.3-12), at the lower end of the canyon near the Mortandad Canyon confluence, are consistently low (less than 10 mg/L). However, pore-water concentrations exceed 1000 mg/L in the shallow part of borehole 35-2028 in Pratt Canyon, while concentrations are less than 4 mg/L below 12 m (69 ft) in this borehole. The 35-2028 results are indicative of releases to the Ten Site drainage; however, the vertical extent of nitrate is interpreted to be a function of relatively small mass and/or the lack of a continuous aqueous driver in Pratt and Ten Site Canyons.

Nitrate in the Regional Aquifer

Anthropogenic nitrate has been detected in the regional aquifer beneath Mortandad Canyon. Nitrate concentrations in filtered samples occur at 2 to 2.5 mg/L at R-15 during the 2000 to 2005 period, as shown in Figure 7.2-22. Isotopic analyses of the groundwater at R-15 suggest that nitrate is not significantly fractionated, having δ^{15}N ratios ranging from –0.8 to +1.3‰ (Longmire 2002, 72614). These values are characteristic of nitrate derived from neutralized nitric acid (Broxton et al. 2001, 71252), most likely released from TA-50 RLWTF. Nitrate concentrations varied from 3.10 to 4.89 mg/L at R-28 in 2005, as shown in Figure 7.2-23. These are the highest concentrations of nitrate measured in the regional aquifer beneath Mortandad Canyon. δ^{15}N values for several samples collected from R-28 ranged from 5.51 to +11.88‰, suggesting that nitrate is fractionated and was derived from a sewage source enriched in nitrogen-15 (Clark and Fritz 1997, 59168). Two potential sources of sewage-derived nitrate include the TA-35 lagoons within Ten Site Canyon and sanitary effluent discharges into Sandia Canyon. The Sandia Canyon source is considered most likely caused by the collocation at R-28 of chromium contamination

also thought to have its source in Sandia Canyon. The vadose-zone moisture content and nitrate profiles (Figures 7.2-11 and 7.2-19) at these two wells support the concept of different transport pathways (and hence possible different sources) for the nitrate in the regional aquifer at these locations. Elevated moisture contents and pore-water nitrate concentrations from core obtained during drilling of R-15 extent down into the Otowi Member and into a perched-intermediate zone within the Cerros del Rio basalt, indicating further downward migration of water and nitrate to the regional aquifer from the TA-50 source. Drier conditions and very little nitrate are observed in the vadose zone at R-28, indicating little vertical migration at that location. Nitrate in the regional aquifer at R-28 probably entered the regional aquifer upgradient and arrived at the well by horizontal flow within the regional aquifer.

Several other regional aquifer wells sampled during this investigation had nitrate concentrations of less than 1.0 mg/L including R-1, R-13, R-14, R-33, R-34, and TW-8. Concentrations of nitrate plus nitrite(N) were less than analytical detection (<0.05 mg/L) in four samples collected at R-14. The majority of groundwater samples analyzed from R-14 contained detectable nitrate plus nitrite. The nondetections are most likely due to the presence of residual drilling fluid in screen 2.

The spatial extent of nitrate detected in the regional aquifer correlates with the nitrate mass observed in the vadose zone.

Perchlorate

Perchlorate is detected in surface water, alluvial and perched-intermediate groundwater, and the regional aquifer beneath Mortandad Canyon. Perchlorate has been discharged into Mortandad Canyon from the TA-50 RLWTF outfall probably since 1963. The primary source of perchlorate is from perchloric acid ($HClO_4$), a strong oxidizing acid used in actinide research and processing at the Laboratory. Perchlorate is mobile and stable as an anion in groundwater and does not significantly adsorb onto clay minerals, ferric (oxy)hydroxide, solid organic matter, nor other naturally occurring adsorbents. Filtered and nonfiltered results are combined in the discussions that follow because filtration has little to no effect on measured perchlorate concentration.

Perchlorate in Surface Water and Alluvial Groundwater

Perchlorate travels laterally downcanyon with the surface water and alluvial groundwater in the watershed. The spatial trends in recent (2000–2005) perchlorate concentrations in surface water and alluvial groundwater are shown in the box plots of Figures 7.2-24 (a–c). In upper Mortandad Canyon (Figure 7.2-24(a)), in upper Effluent Canyon (Figure 7.2-24(b)), and in Ten Site Canyon (Figure 7.2-24(c)) the perchlorate concentrations are low (<10 μg/L), indicating that there are no recent perchlorate sources contributing to the perchlorate mass already in these canyon segments. The perchlorate concentration at surface water station E-1E SW in Effluent Canyon (Figure 7.2-24(b)) does not show an increase to indicate a TA-50 RLWTF outfall source; however, these data were all collected in 2005, approximately 3 yr after perchlorate treatment was improved at the TA-50 RLWTF and concentrations were greatly reduced in effluent (see Section 2.1.1). Perchlorate concentrations are higher in Mortandad Canyon beyond the confluence with Effluent Canyon (Figure 7.2-24(a)), indicating that previous perchlorate releases from the TA-50 RLWTF outfall were the primary source of perchlorate to the watershed. Figure 7.2-24(b) shows a trend of increasing concentration spatially from west to east in Mortandad Canyon beyond the Effluent Canyon confluence similar to that observed for nitrate. As for nitrate, this trend is indicative of a dilution lag in the alluvial aquifer from west to east since improved perchlorate removal began at the RLWTF in 2002 (see Section 2.1.1), with the lag being a function of both the distance from the outfall and the volume of alluvial groundwater storage.

Figure 7.2-25 is a time series plot covering the period 2000 through 2005 when perchlorate concentrations were regularly measured and removal of perchlorate from the TA-50 RLWTF effluent occurred. The plot shows annual perchlorate concentration in the effluent and the resulting concentrations at alluvial wells MCO-3, MCO-5, MCO-6, MCO-7, and MCO-7.5. Outfall perchlorate concentrations have dropped from 257 and 305 μg/L in 2000 and 2001, respectively, to nondetect since 2003 (LANL 2005, 91523). Correspondingly, concentrations in the alluvial wells have declined to values ranging from about 10 to 50 μg/L in 2005. Alluvial concentrations should continue to decline in response to the greatly reduced perchlorate concentrations in the effluent, with a lag similar to those seen in the nitrate responses at corresponding alluvial wells (Figure 7.2-18).

Perchlorate in Vadose-Zone Pore Water and Perched-Intermediate Groundwater

Perchlorate has migrated from the surface water and alluvial groundwater into the vadose zone. The vertical extent of perchlorate contamination in the vadose zone is similar to nitrate in most of Mortandad Canyon, as depicted in Figure 7.2-26 and in Appendix D (Figures D-2.3-1 through D-2.3-21). The collocation is likely an indication of the same release site (TA-50 RLWTF) and similar release histories. Within a given borehole, perchlorate and nitrate concentrations are often highly correlated with depth (for example, see Figures D-2.3-16 and D-2.3-20), and within some boreholes, correlation coefficients between perchlorate and nitrate are above 0.9. These correlations suggest a similar long-term release history for the two contaminants and similar transport rates in the vadose zone. Correlations tend to be poorer in the alluvium. However, this is a zone where variable mixing of recharge water and some denitrification is likely occurring (LANL 2005, 91696). In contrast, there is no evidence for natural perchlorate degradation in Mortandad Canyon (e.g., no chlorate and chlorite, byproducts of perchlorate degradation).

Until 1999, no records were kept for perchlorate in the TA-50 RLWTF effluent. The present-day distribution of perchlorate mass is estimated from the interpolated concentration data shown in Figure 7.2-26 in the same manner that is used to estimate the nitrate mass (Appendix I). Table 7.2-5 lists the approximate in situ perchlorate mass as 1248 kg and includes the distribution by stratigraphic interval. As for nitrate, nearly the entire perchlorate mass (95.6%) is estimated to be in the vadose-zone pore water within and stratigraphically above the Otowi Member. Only 2.6% and 1.7% of the mass are estimated to be in the alluvial groundwater and perched-intermediate groundwater, respectively.

The vadose-zone distribution of perchlorate is also quite similar to that of nitrate. Perchlorate concentrations are mostly below analytical detection in Effluent Canyon (MCB-1 and MCB-2, Figures D-2.3-1 and D-2.3-2), but concentrations are significantly higher where the canyon widens near the Ten Site Canyon confluence (from MCB-5 downcanyon), which also supports the conceptual model shown in Figure 7.0-1. There is one notable exception to the similarity in horizontal extent between nitrate and perchlorate. In contrast to nitrate, the zone of little to no perchlorate beyond borehole MCOBT-8.5 depicted in Figure 7.2-26 is probably real. In fact, pore-water perchlorate results suggest that there is not much perchlorate from approximately AHF borehole MC-1 eastward to the Laboratory boundary. Pore-water concentrations for boreholes MC-1, -2, -3, and MCB-16 (Figure D-2.3-13) show no perchlorate detections, and there were only two isolated detections in pore water in R-28 (Figure D-2.3-21). Note that the sample preservation problems with the AHF MC boreholes mentioned in Appendix M would increase estimated concentrations.

It is possible that a continuous area of perchlorate contamination occurs in the vadose zone between MCOBT-8.5 and R-28 in the mid- to lower-Otowi Member because the MC holes were only drilled to the top of the Otowi Member. However, the limited detections and low perchlorate concentrations at R-28

suggest that the zone of contamination becomes discontinuous somewhere between MCOBT-8.5 and R-28.

Perchlorate also occurs in perched-intermediate groundwater beneath Mortandad Canyon. Perchlorate concentrations increased from 32.1 to 256 μg/L at perched-intermediate well MCOBT-4.4 sampled from 2001 to 2005 (Figure 7.2-21). Concentrations of perchlorate collected at MCOI-4 varied from 134 to 159 μg/L during 2005 (Figure D-2.2-16(g)). Perchlorate concentrations at MCOI-4 are lower than those observed at MCOBT-4.4, even though the two wells are close to each other and screened across the same zone in the Puye Formation. At well MCOI-5, perchlorate concentrations generally increased from 81.6 to 104 μg/L during 2005 (Figure D-2.2-17(g)). Concentrations of perchlorate at MCOI-6 varied from 159 to 246 μg/L during 2005 (Figure D-2.2-18(g)).

Occurrence of perchlorate in Ten Site Canyon is different than that observed for nitrate. Although nitrate was observed at low concentrations (<10 mg/L) in core collected for well R-14 in upper Ten Site Canyon, perchlorate concentrations are elevated to a depth of 90 m (300 ft) with maximum pore water concentrations over 200 μg/L (Figure D-2.3-19). Perchlorate was also detected in pore water down to 27 m (90 ft) in borehole 35-2028 in Pratt Canyon, and some concentrations exceeded 500 μg/L. In addition, there were two chlorate detections in the upper 27-m (90-ft) zone, and these are the only chlorate detections observed in the entire Mortandad watershed borehole data set. It is possible that the chlorate is an in situ perchlorate degradation product. It is also possible that it is a remnant of an older radiochemistry process similar to that used at TA-21. This difference in observations for nitrate and perchlorate indicates that there was not a Ten Site Canyon nitrate source that was correlated to the apparent perchlorate source.

The R-14 and 35-2028 results show that there were historical releases of perchlorate into the Ten Site drainage, likely through Pratt Canyon. This is also supported by the results from MCB-15 at the bottom of Ten Site Canyon where perchlorate concentrations up to 37 μg/L in pore water are observed (Figure D-2.3-12). The MCB-15 profile shows that there are two distinct intervals of perchlorate contamination, one extending from 3 to 6 m (11 to 21 ft) (and possibly shallower) and the other extending from 40 to 46 m (131 to 151 ft) (and possibly deeper). The upper zone is within the alluvium and does not extend past the contact with unit Qbt1g tuff. The top of the deeper zone lies roughly 9 m (30 ft) below the top of the Otowi Member. It is not clear why these isolated zones are present, but there are some alternative hypotheses. The shallow zone probably developed from surface water infiltration or episodic alluvial groundwater migration within Ten Site Canyon, similar to that observed in Mortandad Canyon. An explanation for the contamination in the deeper interval is less clear. It could represent a deeper, but separate, flow path within Ten Site Canyon or a lateral southward flow component from Mortandad Canyon, given the proximity between the two canyons.

Perchlorate in the Regional Aquifer

Perchlorate released from TA-50 has migrated to the regional aquifer in Mortandad Canyon. The highest concentrations of perchlorate were measured at R-15. Concentrations of perchlorate at R-15 generally increased from 4.71 to 6.39 μg/L from 2003 to 2005 (Figure 7.2-22). Concentrations of perchlorate at R-28 ranged from 0.99 to 1.13 μg/L during 2005 (Figure 7.2-23). Concentrations of perchlorate are observed at R-1, R-13, R-33, R-34, and TW-8 (see Appendix D, Section D-2.2) were much lower than those observed at R-15 and R-28. Detectable concentrations of perchlorate, analyzed by liquid chromatography-mass spectrometry/mass spectrometry (EPA SW846 modified Method 6850) to obtain a lower detection limit, ranged from 0.12 to 0.48 μg/L at R-1, R-13, R-14, R-33, R-34, and TW-8. Concentrations of perchlorate were less than analytical detection (<0.05 μg/L) in three samples collected at R-14 (screen 2). The nondetects of low-level perchlorate are most likely due to the presence of residual

drilling fluid in screen 2, R-14. The spatial extent of perchlorate detected in the regional aquifer correlates with the perchlorate mass observed in the vadose zone.

Chromium

Chromium is detected in surface water, alluvial and perched-intermediate groundwater, and the regional aquifer beneath Mortandad Canyon. Chromium speciation controls its mobility in groundwater.

- Chromium(VI) is soluble as anions and is subsequently mobile in oxidizing groundwater. Chromium(VI), in the form of potassium dichromate ($K_2Cr_2O_7$), was used in cooling towers at the TA-03 power plant as a corrosion inhibitor from approximately 1956 to 1972 (LANL 2006, 91987), and cooling tower blowdown (effluent) was released into Sandia Canyon. It may have been used in other cooling towers at TA-03, TA-35 and TA-48 with blowdown released directly to the Mortandad watershed as well. Chromic acid may also have been used in electroplating operations at facilities on Sigma Mesa at TA-03 (LANL 2006, 91987). Both potassium dichromate and chromic acid dissociate to the anions CrO_4^{2-} and $HCrO_4^-$, which are hypothesized to be the dominant mobile species in surface water and groundwater. Chromium(VI) is the dominant species when concentrations of chromium in filtered and nonfiltered sample pairs are similar.
- Chromium(VI) can be reduced to chromium(III) in the presence of reducing agents, such as solid organic matter present within wetlands and alluvial sediments and ferrous iron within glass, silicates, and oxides in the alluvium and Cerros del Rio basalt. Once reduced, the chromium(III) is insoluble and precipitates from solution as amorphous or crystalline $Cr(OH)_3$ and co-precipitates with ferric iron as $(Fe_xCr_{1-x})(OH)_3$ (Rajet et al 1987, 91686; Raji and Zachara 1986, 91684) and is subsequently much less mobile in groundwater. Below pH 7, chromium(III) is stable as a cation that adsorbs onto solid organic matter. In any of these phases, chromium(III) is associated with suspended particles present in nonfiltered samples. Chromium(III) is the dominant species when chromium concentrations in nonfiltered samples exceed those in filtered samples.

The role of speciation on chromium mobility will be further evaluated under the “Interim Measures Work Plan for Chromium Contamination in Groundwater” (LANL 2006, 91987) and under subsequent related work plans as appropriate.

Chromium in Surface Water and Alluvial Groundwater

The spatial trends in recent (2000–2005) total (nonspeciated) chromium(III and VI) concentrations in surface water and alluvial groundwater are shown in box plots in Appendix D, Figures D-2.1-7 through D-2.1-9, for different portions of the Mortandad watershed. Box plots for both filtered (dissolved) and nonfiltered (dissolved and suspended fractions) samples are presented separately because filtration tends to remove trivalent chromium from the sample and thus allows speciation information to be gleaned from the total chromium analyses, as discussed above. The spatial distributions of chromium concentrations shown in Figures D-2.1-7 through D-2.1-9 indicate that chromium in surface water and alluvial groundwater in the Mortandad watershed are predominantly, if not entirely, Laboratory derived.

At the heads of Mortandad Canyon (Figure D-2.1-7) and Effluent Canyon (Figure D-2.1-8), and throughout Ten Site Canyon (FigureD-2.1-9), total chromium concentrations in surface water and alluvial groundwater are higher than at downstream locations, indicating that separate chromium sources are discernible in reaches at the heads of these canyons. At each of these locations, chromium(III) dominates over chromium(VI) in the surface water and alluvial groundwater samples because the nonfiltered fraction constitutes the majority of total chromium. In upper Mortandad Canyon, the highest chromium concentrations occur in surface water below TA-03 within reach M-1W where total chromium was

observed at 27.5 μg/L in a nonfiltered water sample. In Effluent Canyon, the highest concentration of total chromium is 100 μg/L in a nonfiltered alluvial groundwater sample collected at MCO-2/MCA-4 west of (above) the TA-50 outfall. In Ten Site Canyon, total chromium is identified in surface water within reaches TS-1C, TS-2C, and TS-2E (Figure D-2.1-9). The maximum detected concentration of total chromium is 20.8 μg/L in surface water in reach TS-1C. The higher apparent presence of chromium(III) in the upper portions of these canyon segments indicates that the chromium(III) is relatively immobile and is probably related to the presence of chromium(III)-contaminated sediments redistributed downcanyon of small historical sources at TA-03, TA-48, and TA-35 (Section 2.1). The predominance of chromium(III) in that area is also likely related to the several small wetlands that exist within the canyon floor in that area. The concentrations and frequency of detection generally decrease east of the TA-50 RLWTF outfall in Effluent Canyon and in Mortandad Canyon past the confluence with Effluent Canyon. From reach E-1W eastward, low-detected concentrations of total chromium occur in surface water and alluvial groundwater. Although chromium(III) dominates in the samples, detection of chromium in both filtered and nonfiltered samples indicates the co-occurrence of chromium(III and VI) in the surface water and groundwater samples. Concentrations in filtered samples of both surface water and alluvial groundwater do not exceed 50 μg/L or 100 μg/L, the NMWQCC groundwater standard and EPA Region 6 drinking water MCL, respectively.

Chromium in Vadose-Zone Pore Water and Perched-Intermediate Groundwater

The hypothesis for chromium transport in the vadose zone is that chromium(VI) migrates from the alluvial groundwater into the vadose zone and travels as the mobile anions CrO_4^{2-} and $HCrO_4$. Chromium(VI) can be reduced to chromium(III) along vadose zone flow paths by naturally occurring minerals and volcanic glass that act as reducing agents. Ferrous iron concentrated within the Cerros del Rio basalt is considered to be another potential reductant for chromium(VI). Once reduced, chromium(III) precipitates from solution or adsorbs onto ferric (oxy)hydroxide and clay minerals.

Analytical results for chromium and iron measured on vadose-zone core samples are plotted in Appendix D, Figures D-2.4-1 through D-2.4-21. Potential anthropogenic chromium was identified in the core samples at concentrations exceeding background for the Bandelier Tuff-Cerro Toledo Interval (2.24 to 7.14 mg/kg) and/or sediments (10.5 mg/kg) (Ryti et al. 1998, 59730) at MCB-2, -7, -8, -9, -10, -11, -12, -14, -15, and -16, R-14, and R-15. Chromium is found concentrated at or near the interfaces of the alluvium with Unit Qbt1g and of Unit Qbt1g with the Cerro Toledo Interval (Figures D-2.4-1 through 2.4-21). The highest concentration of anthropogenic chromium (440 mg/kg) was detected in core collected at R-15 at a depth of 37 m (120 ft) at the contact between the Cerro Toledo Interval and Otowi Member of the Bandelier Tuff (Figures D-2.4-20 and D-2.4-21) (Longmire et al. 2001, 70103). With respect to the MCB boreholes, the highest concentration of anthropogenic chromium (71 mg/kg) was detected at MCB-14 at a depth of 66 m (215 ft) (Figure D-2.4-11) within the Otowi Member of the Bandelier Tuff. In fact, MCB-14 contains the greatest chromium mass of any borehole with five measured chromium concentrations above 15 mg/kg over the depth interval 52 to 82 m (170 to 270 ft). Excluding the sample from core collected at R-15, core samples from the remainder of the boreholes did not have chromium concentrations exceeding 15 mg/kg. Concentrations of chromium are within background at MCB-1, MCB-5, and MCB–6.

Analysis conducted on core samples did not differentiate chromium(III) from chromium(VI). However, because of the ability of iron-bearing minerals to reduce and then adsorb chromium(III), the co-occurrence of chromium and iron is indicative of adsorbed chromium(III). The chromium and iron profiles (Figures D-2.4-1 through D-2.4-21) indicate a strong correlation between chromium and iron, that is, higher chromium concentrations are collocated with higher iron concentrations, meaning that the chromium is likely relatively immobile. Under acidic pH conditions, CrO_4^{2-} and $HCrO_4^-$ adsorb onto ferric

(oxy)hydroxide to a greater extent than under alkaline pH conditions. Therefore, chromium(VI) may partly account for some of the association between iron and chromium in the unsaturated zone.

Elevated chromium(VI) concentrations are observed in perched-intermediate zones located beneath Mortandad Canyon. The presence of deep contamination indicates that there are some preferential pathways through the vadose zone that have transported comparatively small masses of chromium to depths below the Otowi Member. Perched-intermediate wells sampled during 2005 include MCOI-4, MCOI-5, MCOI-6 (Figures D-2.2-16[a], D-2.2-17[a], and D-2.2-18[a]), and MCOI-8, whereas MCOBT-4.4 (Figure 7.2-21) was sampled from 2001 to 2005. The data show spatially variable results with chromium(VI) dominating in some of the perched zones and chromium(III) at others.

Concentrations of total chromium in filtered and nonfiltered samples decreased from 53.3 to 37.4 μg/L and 53.6 to 41.4 μg/L, respectively, at perched-intermediate well MCOBT-4.4 during 2002 and 2003 (Figure D-2.2-15[a]). Concentrations of total chromium in filtered and nonfiltered samples were similar, indicating that chromium(VI) dominants over chromium(III) at MCOBT-4.4.

Concentrations of total chromium in nonfiltered samples collected at MCOI-4 in 2005 have decreased from 135 to 61.3 μg/L (Figure D-2.2-16[a]) and sample turbidity decreased from 31.9 to 18 nephelometric turbidity units (NTUs). Total chromium in filtered samples increased from 25 to 29.4 μg/L in the samples during 2005. Concentrations of total chromium in nonfiltered samples initially exceeded those in filtered samples suggesting that chromium(III) dominates.

Concentrations of total chromium in nonfiltered samples collected at MCOI-5 in 2005 decreased from 770 to 545 μg/L (Figure D-2.2-17[a]) and sample turbidity decreased from 83.6 to 16.6 NTU. This well is located on the south side of Mortandad Canyon near regional aquifer well R-15. Concentrations of total chromium in filtered samples at the well also decreased from 3.5 to 3.1 μg/L. This suggests that chromium(III) dominates and that chromium(VI) represents a small fraction not removed from solution by adsorption and/or precipitation processes.

Concentrations of total chromium in nonfiltered samples at MCOI-6 in 2005 were 52.2 to 58.9 μg/L (Figure D-2.2-18[a]) and sample turbidity was 4.86 and 6.41 NTU. Concentrations of total chromium in filtered samples collected at the well also increased from 48.4 to 58.2 μg/L, suggesting that chromium(VI) dominates. Variation in total chromium in nonfiltered samples is caused by the presence of suspended particles that probably contain natural and anthropogenic chromium(III). Well MCOI-8 was sampled for chromium in 2006, and analytical results will be reported in the "Chromium Interim Measures Report."

Overall, perched-intermediate groundwaters from MCOBT-4.4, MCOI-4, and MCOI-6 have elevated chromium(VI), represented by total chromium concentrations in filtered samples, ranging from 25 to 58 μg/L that is most likely anthropogenic. Suspended particles in these samples probably contain both natural and anthropogenic chromium(III). Chromium(VI) concentrations, represented by total chromium concentrations in filtered samples in intermediate groundwater from MCOI-5 are low at 3.5 μg/L or less. This well may not be impacted by anthropogenic sources.

Chromium in the Regional Aquifer

Regional aquifer wells sampled during this investigation included R-1, R-13, R-14, R-15, R-28, R-33, R-34, and TW-8 (see Appendix D, Section 2.2). Concentrations of total chromium within the regional aquifer in the Puye Formation are the highest beneath the axis of Mortandad Canyon at R-28 (Figure 7.2-23) and decrease to the southeast and southwest at R-13 (Figure D-2.2-20[a]) and R-15. (Figure 7.2-22).

Concentrations of total chromium at R-15 varied from 3.6 to 14.7 μg/L in nonfiltered samples collected from 1999 to 2005 (Figure D-2.2-22[a]). Concentrations of total chromium varied from 2.6 to 7.9 μg/L in filtered samples at the well (Figure 7.2-22 and D-2.2-22[a]). Concentrations of total chromium at R-28 generally increased from 375 to 404 μg/L (Figure 7.2-23) and from 389 to 416 μg/L (Figure D-2.2-23[a]) in filtered samples and nonfiltered samples, respectively, collected during 2005. These are the highest concentrations of total chromium(III, VI) and chromium(VI) measured in the regional aquifer beneath the Laboratory. Detectable concentrations of total chromium in nonfiltered and filtered samples ranged from 2.73 to 12.3 μg/L and from 0.93 to 8.2 μg/L, respectively, at R-1, R-13, R-14, R-33, and R-34 (Appendix D, Section D-2.2). Concentrations of total chromium varied from 3.36 to 7.92 μg/L in nonfiltered samples collected at TW-8 from 2001 to 2005 (Figure D-2.2-26[a]). Concentration of total chromium in three filtered samples were less than analytical detection (<1 μg/L) at R-14 (Figure D-2.2-21[a]) in 2004 and 2005. The majority of water samples from R-14 contained detectable total chromium. The nondetection of total chromium is most likely due to the presence of residual drilling fluid in screen 2, R-14.

Iron

Solid and aqueous species of iron occur within stream sediments, alluvial and perched-intermediate groundwater, the regional aquifer, and unsaturated and saturated rock. Under oxidizing and circumneutral pH conditions, such as in the Mortandad watershed, ferric iron precipitates from solution typically as insoluble ferric (oxy)hydroxide and ferric oxide (hematite) (Langmuir 1997, 56037). Iron is stable in the +II (ferrous) and +III (ferric) oxidation states in aqueous solution and forms complexes with hydroxide, sulfate, chloride, and bicarbonate. These complexes influence the solubility of iron(II, III) solids. Ferric (oxy)hydroxide is an important adsorbent for many trace elements and radionuclides, including americium, arsenic, cadmium, chromate, cobalt, lead, nickel, plutonium, selenium, thorium, uranium, and zinc. The specific surface area of hydrated ferric hydroxide (ferrihydrite) is 600 m^2/g as compared with that of quartz having a value of 0.14 m^2/g (Langmuir 1997, 56037). Iron(III) dominates over iron(II) when concentrations of iron in nonfiltered samples exceed those of filtered samples. Iron and manganese have similar chemical properties, and iron is typically collocated with manganese in sections of the Mortandad watershed. Under reducing conditions enhanced by the presence of residual organic-based drilling fluids, iron(III) solids dissolve and iron(II) aqueous species and solids becomes stable. Desorption of trace elements can take place during reductive dissolution of ferric (oxy)hydroxide, resulting in an increase of these solutes in groundwater.

Iron in Surface Water and Alluvial Groundwater

The spatial trends in total (nonspeciated) iron(II and III) concentrations in surface water and alluvial groundwater from 2000-2005 are shown in box plots in Appendix D, Figures D-2.1-10 through D-2.1-12, for different portions of the Mortandad watershed. Box plots for both filtered (dissolved) and nonfiltered (dissolved and suspended fractions) samples are presented separately to help differentiate speciation. The highest concentrations of total iron in nonfiltered samples are measured within reach M-1W (25.5 mg/L, Figure D-2.1-10) in upper Mortandad Canyon just east of TA-03 (Plate 1) and at well MCO-2/MCA-4 (26 mg/L) in Effluent Canyon (Figure D-2.1-11). Most of the iron at these locations occurs as a precipitate associated with suspended material because concentrations of total iron in nonfiltered samples are greater than total iron in filtered samples. Surface water at reach E-1W is also elevated (approximately 5 mg/L in both nonfiltered and filtered samples). Concentrations of total iron are much lower in surface water and alluvial groundwater within Mortandad Canyon east of the Effluent Canyon confluence (Figure D-2.1-11). These distributions indicate sources at the head of Mortandad Canyon in TA-03 and to Effluent Canyon west of the TA-50 RLWTF outfall.

In Ten Site Canyon, the highest concentration of iron is identified in surface water within reach TS-1C (Figure D-2.1-12). Iron(III) precipitate(s) associated with suspended material dominate within this reach because concentrations of total iron in nonfiltered samples greatly exceed dissolved iron in the surface-water samples. Concentrations of total iron in nonfiltered samples decrease downcanyon to the Mortandad confluence (Figure D-2.1-12). Concentrations of iron detected in surface water in reach TS-1C are possibly related to the presence of iron-contaminated sediments redistributed down canyon of the TA-35 source. Ferric chloride and ferric sulfate were identified as chemicals present in the TA-35 wastewater or used to treat the wastewater before discharge (LANL 1997, 56835).

Iron in Vadose-Zone Pore Water, Perched-Intermediate Groundwater, and the Regional Aquifer

Analytical results for iron measured on vadose-zone core samples are plotted in Figures D-2.4-1 through D-2.4-21. Background concentrations of iron range from 0.37 to 1.45 wt% within the Bandelier Tuff and are 1.38 wt% in sediments (McDonald et al. 2003, 76084; Ryti et al. 1998, 59730). Background concentrations of iron are observed at MCB-1, MCB-2, MCB-5, MCB-6, MCB-14, and MCB-16, R-14, and R-15. Concentrations of iron exceeding background occur at MCB-7, MCB-8, MCB-9, MCB-10, MCB -11, MCB -12, and MCB-15, which could be represented by a combination of anthropogenic and natural iron in the forms of ferric (oxy)hydroxide, Fe_2O_3 (hematite) and Fe_3O_4 (magnetite) The co-occurrence of iron and chromium, as discussed in the chromium section above, suggests that adsorption processes are important in concentrating chromium within the vadose zone.

Anthropogenic forms of iron discharged from the Laboratory most likely have not migrated to perched-intermediate zones and the regional aquifer because of the elements' low solubility under circumneutral pH and oxidizing conditions dominant in the subsurface. Distributions of natural iron in the deeper saturated zones are controlled by specific hydrogeochemical conditions including redox conditions, groundwater composition, and aquifer mineralogy. Biologically induced breakdown of drilling fluids results in reductive dissolution of ferric (oxy)hydroxide and hematite (LANL 2005, 91533). Concentrations of total dissolved and total iron range from 2.33 and 4.50 mg/L and 4.24 and 6.85 mg/L, respectively, at R-14 (screen 2). Elevated concentrations of dissolved iron show the presence of residual drilling fluid at the well.

Fluoride

Fluoride has been detected in surface water, alluvial and perched-intermediate groundwater, and the regional aquifer within the Mortandad watershed. There are both natural and anthropogenic sources of fluoride within the watershed, with Laboratory-derived fluoride produced from the dissociation of hydrofluoric acid that is neutralized before discharge. Fluoride has been released at the TA-50 RLWTF outfall, but since 2000, effluent concentrations have been below the New Mexico WQCC groundwater standard of 1.6 mg/L, and in 2005 the average concentration had dropped to 0.24 mg/L (LANL 2006, 93925). Fluoride is mobile in groundwater as an anion and does not significantly adsorb onto clay minerals, ferric (oxy)hydroxide, solid organic matter, and other naturally occurring adsorbents. In the presence of calcium, fluoride precipitates from solution as CaF_2 (fluorite), and its solubility is independent of pH.

Fluoride in Surface Water and Alluvial Groundwater

Fluoride travels laterally downcanyon with surface water and alluvial groundwater in the watershed. The spatial trends in recent (2000–2005) fluoride concentrations in nonfiltered samples of surface water and alluvial groundwater are shown in box plots in Appendix D, Figures D-2.1-13 through D-2.1-15, for different portions of the Mortandad watershed. Fluoride was detected in all surface water samples

collected within upper Mortandad Canyon west of the Effluent confluence (Figure D-2.1-13). The highest concentration of fluoride was 0.72 mg/L measured in reach M-1W. Concentrations of fluoride decrease in surface water to the Effluent Canyon confluence and then increase downcanyon (Figure D-2.1-14). The maximum concentrations of fluoride are 1.92 mg/L at wells MT-1 and MT-3 in 2005, just slightly over the New Mexico WQCC groundwater standard of 1.6 mg/L. In Ten Site Canyon, detectable concentrations of fluoride are low, ranging between 0.03 and 0.42 mg/L in surface water samples. Effluent from the TA-50 RLTWF has been a source of fluoride to the watershed. However, it appears that fluoride has also entered the watershed at TA-03 and may have come from TA-48 (to both Mortandad and Effluent canyons) as well.

The overall distribution of fluoride concentrations in surface water and alluvial groundwater is very similar to that observed for nitrate. That is, fluoride concentrations increase spatially from west to east in Mortandad Canyon beyond the Effluent Canyon confluence. As for nitrate, the trend is indicative of a dilution lag in the alluvial aquifer from west to east since improved effluent quality in 2000 (Section 2.1.1). The lag is caused by the distance from the outfall and to increasing alluvial storage from west to east (Section 7.2.1.2). Time series plots for surface water at gage E200 (Figure D-2.2-1[b]) and several alluvial wells (e.g., Figures D-2.2-6[b], D-2.2-7[b], D-2.2-9[b]) show a decline in fluoride concentrations since 2000. In 2005, only the most distal alluvial wells, MCOBT-7.5, MT-1, and MT-3 have concentrations slightly over the New Mexico WQCC groundwater standard (1.92 mg/L vs. 1.6 mg/L). None of the surface water or alluvial water concentrations is currently above the EPA Region 6 tap water standard of 4 mg/L. Over time, fluoride concentrations at the alluvial wells will decline even further in response to improved effluent quality at the TA-50 outfall and to dilution by occasional surface water runoff events.

Fluoride in Vadose-Zone Pore Water and Perched-Intermediate Groundwater

Fluoride appears to have mobility similar to nitrate in the vadose zone and is present in vadose-zone pore water into the Otowi Member and at a few locations is present in perched-intermediate groundwater. For instance, at wells MCOBT-4.4 and MCOBT-8.5, pore-water concentrations of fluoride range from approximately 4 to 20 mg/L throughout the Otowi Member (Broxton et al. 2002, 76006). Concentrations of fluoride have varied within the perched-intermediate zones from 2002 to 2005, which may be indicative of natural conditions with a slight impact from the TA-50 outfall. Concentrations of fluoride in filtered and nonfiltered samples slightly varied from 0.4 to 0.42 mg/L at MCOBT-4.4 during 2002 and 2003. At MCOI-4, concentrations of fluoride in nonfiltered samples varied from 0.21 to 0.24 mg/L. At MCOI-5, concentrations of fluoride in filtered and nonfiltered samples increased from 0.24 to 0.33 mg/L. Concentrations of fluoride in filtered and nonfiltered samples at MCOI-6 increased slightly from 0.54 to 0.59 mg/L during 2005.

Fluoride in the Regional Aquifer

Fluoride within the regional aquifer beneath Mortandad Canyon is generally variable within a narrow concentration range. Concentrations ranged from 0.01 to 0.48 mg/L, representing natural conditions within the regional aquifer.

Lead

Lead is a naturally occurring trace metal found in surface water and groundwater environments. It is also a widespread environmental contaminant associated with industrial discharges, bullets, batteries, leaded gasoline, paint, solder, and other waste forms or chemicals. Lead is stable in the +II oxidation state in aqueous solution (Langmuir 1997, 56037) and forms complexes with hydroxide, sulfate, chloride, and bicarbonate. Lead also precipitates from solution in the form of hydroxide, carbonate, sulfate, and

phosphate minerals. Lead strongly adsorbs onto ferric (oxy)hydroxide through surface complexation reactions (Langmuir 1997, 56037) under circumneutral pH conditions. Lead is very immobile in groundwater if it occurs as a cation and is not complexed with organic ligands or anions.

Lead in Surface Water and Alluvial Groundwater

The spatial trends in recent (2000–2005) lead concentrations in nonfiltered samples of surface water and alluvial groundwater are shown in box plots in Appendix D, Figures D-2.1-16 through D-2.1-18. The two highest concentrations of lead measured within the Mortandad watershed, exceeded 30 μg/L and 27 μg/L in nonfiltered surface water samples collected in upper Ten Site Canyon (Figure D-2.1-18) and upper Mortandad Canyon (Figure D-2.1-16), respectively. Concentrations of lead in nonfiltered surface water samples lower substantially downcanyon. In Effluent Canyon, the highest concentration of lead (22 μg/L) was measured in a nonfiltered alluvial groundwater sample collected at well MCO-2/MCA-4 above the TA-50 RLWTF outfall (Figure D-2.1-17). A dissolved concentration of lead of 3.5 μg/L was measured at alluvial well MCO-2/MCA-4, located above the Mortandad Canyon confluence. The sources of lead at these locations, which are all near the head of their respective canyons, are most likely anthropogenic, originating from TA-35, TA-03 and TA-48 discharges, respectively, and/or atmospheric and roadside deposition of leaded gasoline that contains tetraethyl lead. Most of the lead within the watershed is associated with suspended material because concentrations of this metal in nonfiltered samples are greater than that found in filtered samples. Concentrations of dissolved lead in surface water and alluvial groundwater within the watershed are less than the New Mexico WQCC groundwater standard of 50 μg/L and the EPA Region 6 tap water standard of 15 μg/L.

Lead in Vadose-Zone Pore Water, Perched-Intermediate Groundwater, and the Regional Aquifer

Anthropogenic forms of lead discharged from the Laboratory most likely have not migrated substantially into the vadose zone and have not reached perched-intermediate zones and the regional aquifer because of the element's high capacity to adsorb onto surfaces of aquifer material containing smectite and ferric (oxy)hydroxide. At well R-15, lead analyses of vadose-zone core samples showed lead within the Bandelier tuff and the Cerro Toledo interval (Longmire et al. 2001, 70103). However, this was attributed to naturally occurring elements within the tuff samples. Detectable concentrations of lead in nonfiltered samples from perched-intermediate zones ranged from 0.56 to 13.8 μg/L at MCOI-4, MCOI-5, MCOI-6, and MCOI–8 and MCOBT-4.4. Dissolved (filtered) concentrations of lead are generally not detected (upper detection limit of 0.5 μg/L) within perched-intermediate zones and the regional aquifer. When detected, dissolved concentrations of this trace metal are less than 0.3 μg/L. Distributions of natural lead in the deeper saturated zones are controlled by specific hydrogeochemical conditions including groundwater composition and aquifer mineralogy. Elevated concentrations of lead may occur in wells resulting from corrosion of components and solder associated with electrical wiring.

Manganese

Manganese is stable in the +II, +III, and +IV oxidation states in aqueous solution in which a large stability field for dissolved Mn(II) occurs (Langmuir 1997, 56037). Manganese (III, IV) solids are stable under oxidizing conditions typical of aquatic environments with little or no dissolved or solid organic matter. Manganese(IV) solids are considered to be important minerals present within aquifer and vadose material in the watershed based on oxidizing conditions. Manganese(IV) solids are important adsorbents for many trace elements similar to that of ferric (oxy)hydroxide (Langmuir 1997, 56037). Manganese (III, IV) oxides are less abundant than ferric (oxy)hydroxide and hematite in aquifer material and surface sediments at the Laboratory based on much higher concentrations of iron (in the weight percent range) than

manganese (in the parts per million range). Manganese has a spatial distribution that is, in part, similar to that of iron in sections of the watershed.

It is widely accepted that bacterially mediated reduction of manganese depends upon sediment moisture conditions, the availability of labile organic carbon, and the presence of poorly crystalline manganese oxides (Lovley 1991, 85523; Lovley and Chapelle 1995, 85506). In wetlands within upper Mortandad Canyon, dissolved and solid organic matter are concentrated in sections with abundant vegetation including grasses, shrubs, cattails, and coniferous and deciduous trees. Persistent saturated conditions in these reaches ensure environmental stability for microbial communities, and abundant manganese oxides associated with volcanic rocks, especially weathered tuffs, on the Pajarito Plateau provide optimal conditions for manganese reduction in wetland pore water. In addition, the slow oxidation kinetics of manganese and the progressively longer residence time of stagnant water within wetlands result in an accumulation of soluble manganese (Hem 1981, 85505).

Manganese in Surface Water and Alluvial Groundwater

The spatial trends in recent (2000–2005) manganese concentrations in nonfiltered and filtered samples of surface water and alluvial groundwater are shown in box plots in Appendix D, Figures D-2.1-19 through D-2.1-21. Concentrations of manganese in filtered and nonfiltered surface water samples range from 6.3 to 958 μg/L and from 7.4 to 1080 μg/L, respectively, within Effluent Canyon. Concentrations of manganese in filtered and nonfiltered alluvial groundwater samples range from 1510 to 2266 μg/L and from 1670 to 2375 μg/L, respectively, at MCA-4. Concentrations of manganese exceeding 2 mg/L are associated with both nonfiltered and filtered samples in surface water in reach M-1E and in alluvial groundwater at MCO-0.6 (Figure D-2.1-19), both located in or near wetland areas in upper Mortandad Canyon west of the Effluent Canyon, and in alluvial groundwater collected from MCO-2/MCA-4 within Effluent Canyon west of the TA-50 RLWTF outfall (Figures D-2.1-20). The presence of abundant wetlands in upper Effluent Canyon and Mortandad Canyon suggests that the manganese observed in this portion of the watershed is naturally occurring. Concentrations of manganese sharply decrease immediately east of the TA-50 outfall and remain low throughout Mortandad Canyon. Most of the detectable manganese is stable as soluble manganese(II) based on similar concentrations within filtered and nonfiltered samples. Concentrations of manganese in filtered and nonfiltered surface water samples range from 1.67 to 33.7 μg/L and from 2.5 to 108 μg/L, respectively, within Mortandad Canyon. Concentrations of manganese in filtered and nonfiltered alluvial groundwater samples range from 0.296 to 7.6 μg/L and from 0.296 to 45.6 μg/L, respectively, within Mortandad Canyon.

In Ten Site Canyon, manganese is identified in surface water within reaches TS-1C and TS-2E (Figure D-2.1-21). The maximum concentrations of total manganese in filtered and nonfiltered water samples are 449 and 1690 μg/L, respectively, in surface water in reach TS-1C. This distribution suggests that particulates of manganese(III, VI) oxides occur within the reach, and the surface water is moderately oxidizing. The maximum concentrations of total manganese in filtered and nonfiltered samples are 875 and 887 μg/L, respectively, in surface water in reach TS-2E. This distribution suggests that manganese(II) is stable and that reductive dissolution of manganese(III, IV) oxides has taken place within the reach. It is not clear whether the manganese in Ten Site Canyon represents a natural condition or a Laboratory source of manganese.

Manganese within Perched-Intermediate Groundwater and the Regional Aquifer

Any anthropogenic forms of manganese that may have been released by the Laboratory most likely have not migrated to perched intermediate zones and the regional aquifer because of the elements' low solubility under circumneutral pH and oxidizing conditions dominating in the subsurface. Distributions of

natural manganese in the deeper saturated zones are controlled by specific hydrogeochemical conditions including redox conditions, groundwater composition, and aquifer mineralogy. Biologically induced breakdown of drilling fluids results in reductive dissolution of manganese oxide (LANL 2005, 91533).

Nickel

Nickel is stable in the +II oxidation state in aqueous solution as Ni^{2+}, $NiHCO_3^+$, and $NiCO_3^0$ (Langmuir 1997, 56037). Free or noncomplexed Ni^{2+} is stable under acidic pH conditions, whereas the complexes $NiHCO_3^+$ and $NiCO_3^0$ are stable under circumneutral pH conditions in the presence of total carbonate alkalinity. Nickel(II) solids, including $Ni(OH)_2$ and $NiCO_3$, are stable under a wide range of redox conditions. Natural nickel is concentrated within the Cerros del Rio lavas, ranging between 35 and 154 ppm (Vaniman et al. 2002, 72615) and is a trace element associated with olivine, basaltic glass, and weathering products such as ferric (oxy)hydroxide, smectite, and iddingsite. Nickel(II) adsorbs onto ferric (oxy)hydroxide and clay minerals (Langmuir 1997, 56037) through surface complexation and cation exchange reactions, respectively.

Elevated concentrations of nickel in filtered and nonfiltered samples were measured at MCOI-5 and R-33 (screen 1) during one or two sampling rounds conducted in 2005. Well MCOI-5 was sampled on June 9 and September 9, 2005. Concentrations of nickel in filtered and nonfiltered samples were 55.8 and 62.2 μg/L and 414 and 282 μg/L, respectively, at MCOI-5. Concentrations of iron in the same filtered and nonfilter samples were 62.4 and 69.8 μg/L and 6980 and 4360 μg/L, respectively, at MCOI-5. Concentrations of iron in nonfiltered samples suggest the presence of iron-rich solid phases associated with suspended material. Turbidity values were 83.6 and 16.6 NTU in the two samples collected on June 9 and September 9, 2005, respectively. Well MCOI-5 is completed within Puye Formation/Cerros del Rio basalt. One hypothesis for explaining the elevated nickel concentrations at MCOI-5 is that natural adsorbents for nickel and other metals such as ferric (oxy)hydroxide, olivine, smectite, and volcanic glass are present as suspended particles.

Well R-33 was sampled on June 24 and 27 and September 14 and 15, 2005. Concentrations of nickel were 168 and 25.1 μg/L, respectively, in filtered and nonfiltered samples collected on June 24, 2005, at R-33 (screen 1) using EPA Method SW-846-6010B. The analytical result for nickel in the filtered sample is suspect because it is greater than that for the nonfiltered sample. The turbidity measured for the sample was 24.1 NTU. Concentrations of iron in the same filtered and nonfilter samples were 163 and 251 μg/L, respectively, which were also analyzed by using EPA Method SW-846-6010B. Other samples collected at R-33 in September 2005 did not show any discrepancies within metal analyses.

7.2.2.2 Organic Chemicals in Water

Aroclor-1260

Aroclor-1260 generally was not detected in surface water and alluvial groundwater samples collected within the Mortandad watershed (Appendix D, Figures D-2.1-22 through D-2.1-24). The maximum instrument detection limit (IDL) for aroclor-1260 was 1.4 μg/L. Arochlor-1260, however, was detected at a concentration of 1.1 μg/L in one nonfiltered surface water sample collected in Ten Site Canyon within reach TS-1C (Figure D-2.1-24). Aroclor-1260 is not considered to be a widespread COPC in surface water or alluvial groundwater within the watershed.

Bis(2-ethylhexyl)phthalate

Bis(2-ethylhexyl)phthalate was detected between concentrations of 0.5 and 7 μg/L in nonfiltered surface water and alluvial groundwater samples within Mortandad Canyon (Appendix D, Figures D-2.1-25 through D-2.1-27). The highest concentration of bis(2-ethylhexyl)-phthalate was measured at well MT-1. The maximum practical quantitation limit (PQL) for bis(2-ethylhexyl)-phthalate is 22 μg/L. Detects of bis(2-ethylhexyl)-phthalate are typically less than the PQLs but are above the minimum detection limit (MDL) of 0.5 μg/L. Bis(2-ethylhexyl)phthalate was observed in regional well R-15 from 2000 to 2005 and in R-33 in 2005 at ranges of 2 to less than 11 μg/L. Bis(2-ethylhexyl)phthalate is a component of plastics and could be derived from several sources, including bailers used during sample collection, Laboratory discharges and runoff, and analytical laboratories in which water samples come in contact with plastic during analysis.

1,4-Dioxane

Perched-intermediate groundwater has shown detections of 1,4-dioxane at MCOI-4 (53.3 and 50.8 μg/L) and MCOI-6 (52.2 and 56.4 μg/L). Other wells sampled in the Mortandad watershed did not contain detectable concentrations of 1,4-dioxane. The analytical detection limit for recent samples analyzed for 1,4-dioxane is 50 μg/L using gas chromatography-mass spectrometry. 1, 4-dioxane is completely miscible in aqueous solution and does not adsorb onto solid surfaces. 1, 4-dioxane is used as a solvent for cellulosics and a wide range of organic products including lacquers, paints, varnishes, paint and varnish removers, cleaning and detergent preparations, cements, cosmetics, deodorants, and fumigants (Verschueren 1983, 63044). The source(s) of 1,4-dioxane have not been identified.

7.2.2.3 Radionuclides in Water

Several radionuclides are identified in Section 6 as being COPCs in surface water, alluvial and perched-intermediate groundwater and/or the regional aquifer in the Mortandad watershed. These include tritium, strontium-90, plutonium-238, plutonium-239,240, and americium-241. A series of plots in Appendix D provides a high-level overview of the spatial trends of the radionuclide COPCs in the Mortandad watershed. The discussion below provides additional information on the spatial distribution of these contaminants in key areas of the watershed. Overall, the spatial distribution of radionuclide concentrations indicates only a few key sources of contaminants in water. The most important sources include the TA-50 outfall within Effluent Canyon and the former TA-35 WWTP outfall adjacent to reach TS-1C in Ten Site Canyon (Plate 1). Ash from the Cerro Grande fire may be a potential minor source of radionuclide constituents measured in water.

Tritium

Tritium is detected in surface water, alluvial groundwater, perched-intermediate groundwater, and the regional aquifer in Mortandad Canyon. Tritium has been discharged into the Mortandad watershed from approximately 1953 to 1974 at TA-35 and since 1963 at the TA-50 RLWTF (see Section 2.1). Tritium is a radioactive isotope of hydrogen with a relatively short half-life of 12.32 yr, which decays to helium-3 with the emission of a beta particle (Clark and Fritz 1997, 59168). It is extremely mobile because it can replace hydrogen within a water molecule and travel as groundwater.

Tritium in Surface Water and Alluvial Groundwater

Tritium travels laterally down canyon with the surface water and alluvial groundwater in the watershed. The spatial trends in recent (2000–2005) tritium concentrations in surface water and alluvial groundwater

are shown in the box plots of Figures D-2.1-28 through D-2.1-30. Tritium concentrations are low (< 1000 pCi/L) in upper Mortandad Canyon (Fig. D-2.1-28), in upper Effluent Canyon (Fig. D-2.1-29), and in Ten Site Canyon (Fig. D-2.1-30) indicating that there is little, if any, recent tritium disposal contributing to these canyon segments. The highest concentrations of tritium in surface water are observed at gage E200 with two detections greater than the groundwater MCL of 20,000 pCi/L. All other surface water and alluvial groundwater detections, except for one high value at well pair MCO-3/MCA-5, are far below the MCL.

Figure 7.2-27 is a time series plot covering the period 1967 through 2005. It shows the annual tritium concentration in TA-50 RLTWF effluent and the resulting concentrations at alluvial wells MCO-3/MCA-5, MCO-5, MCO-6, MCO-7 and MCO-7.5. From 1976 to 1992, the outfall tritium concentrations averaged over 300,000 pCi/L, with maximum concentration exceeding 3,000,000 pCi/L. During this same period, tritium concentrations in the alluvial wells were elevated with many values over 20,000 pCi/L. Since 2001, outfall concentrations have dropped below 20,000 pCi/L. Correspondingly, concentrations of tritium have decreased in surface water and alluvial groundwater.

Current concentrations of tritium in alluvial groundwater are generally higher in the Mortandad Canyon segment between wells MCO-3/MCA-5 and MCO-7.5 (Figure D-2.1-29) are lower east of MCO-7.5. Previous releases from the TA-50 RLWTF are the likely source of tritium. Similar to nitrate and perchlorate, tritium demonstrates a trend of increasing concentration spatially from west to east in Mortandad Canyon beyond the Effluent Canyon confluence. Again, this trend is indicative of a dilution lag in the alluvial aquifer from west to east since improved tritium removal began in 2000 (see Section 2.1.1), with the lag being a function of both the distance from the outfall and localized alluvial storage. To illustrate this, Figure 7.2-28 is a time series plot analogous to Figure 7.2-27, but it covers the period of low tritium effluent concentrations, 2000 through 2004/2005. The observed decline in tritium concentration over time is completely analogous to that observed for nitrate. That is, at the westernmost well pair MCO-3/MCA-5, the concentration decline occurs almost immediately in 2000 after the drop in effluent concentration. At wells MCO-5 and MCO-6, the decline is delayed slightly with the greatest change in 2000 and 2001. Finally, tritium concentrations at the most distal wells, MCO-7 and MCO-7.5, have declined slowly since 2000. Tritium concentrations at these distal locations should continue to decline in response to lower effluent concentrations

Tritium in Vadose-Zone Pore Water and Perched-intermediate Zones

Tritium has migrated from the surface water and alluvial groundwater into the vadose zone. Figures D-2.3-22 through D-2.3-42 show the distribution of tritium concentrations in core samples collected at the MCB-, MCOI- and R- boreholes or wells in the Mortandad watershed. These values are presented here as pore-water concentrations. Both the vertical and horizontal (downcanyon) extent of tritium in the vadose zone is similar to that of nitrate and perchlorate in most of the canyon. This is demonstrated by comparing vadose-zone concentrations for tritium (Figures D-2.3-22 through D-2.3-42) to analogous profiles for nitrate and perchlorate (Figures D-2.3-1 through D-2.3-21). Tritium was detected in core samples collected at 9 of the 13 MCB- boreholes and at MCOI-6, MCOI-8, and MCOI-10, R-1, R-14, R-15, and R-28. A maximum concentration of 3.75×10^6 pCi/L of tritium was measured at MCB-10 at a depth of 18 m (60 ft) within the alluvium. Samples collected at MCB-9, MCB-10, and MCB-11 also had peak concentrations of detectable tritium within the alluvium. At MCB-5, MCB-6, and MCB-7, and R-1, peak concentrations of detectable tritium occur within the Bandelier Tuff, Unit Qbt1g. Peak concentrations of detectable tritium occur within the Cerro Toledo Interval at MCB-8 and MCB-12. The deepest pore-water measurements were observed in the Otowi Member in MCB-14, MCOI-6, MCOI-8, R-1, and R-15, which coincides with that part of Mortandad Canyon below the confluent with Ten Site Canyon and represented as an area with the enhanced deep percolation (Figure 7.0-1). At some locations

(e.g., MCB-14 in Figure D-2.3-32; R-1 in Figure D-2.3-39), tritium does not extend as deep as nitrate and perchlorate, which might be due to radioactive decay in the deepest (and oldest) vadose-zone porewater within the Bandelier Tuff. Tritium was not detected at MCB-1 and MCB-2, west of the RLTWF outfall within Effluent Canyon, or at MCB-15, MCB-16, MCOI-1, or MCOI-10.

Tritium is observed in perched-intermediate groundwater. Concentrations of tritium within saturated portions of the Puye Formation and Cerros del Rio basalt are the highest beneath the axis of Mortandad Canyon east of the confluence with Ten Site Canyon. Concentrations of tritium at MCOBT-4.4 ranged from 9700 to 14,900 pCi/L from 2001 to 2003, when tritium concentrations generally increased over time (Figure 7.2-21). The concentration of tritium was 21,007 pCi/L in a sample collected from the well during 2005. Concentrations of tritium at MCOI-4 varied from 11,700 to 12,900 pCi/L, whereas lower concentrations of tritium occur at MCOI-5 ranging from 4310 to 5370 pCi/L during 2005 (Figures D-2.2-16[l] and D-2.2-17[l]). Concentrations of tritium at MCOI-6 varied from 12,200 to 13,100 pCi/L (Figure D-2.2-18[l]). The concentration of tritium measured at MCOI-8 was 137 pCi/L, confirming that recharge from surface water or perched alluvial groundwater infiltrates to perched-intermediate zones immediately west of the Ten Site confluence.

Tritium in the Regional Aquifer

Based on available data, concentrations of tritium within the regional aquifer in the Puye Formation are the highest beneath the axis of Mortandad Canyon at R-28 and decrease to the south at R-15. Concentrations of tritium at R-28 increased from 152 to 181 pCi/L during 2005 (Figure 7.2-23). These are the highest concentrations of tritium measured in the regional aquifer within Mortandad Canyon. Concentrations of tritium at R-15 increased from 1.12 to 31 pCi/L from 1999 to 2005 (Figure 7.2-21). Concentrations of tritium at regional aquifer well TW-8 varied from 4.21 to 140 pCi/L from 2003 to 2005 (Figure D-2.2-26[l]). TW-8 was drilled by the cable tool method and was completed in 1960, which may have resulted in leakage of alluvial groundwater down the well casing. R-1, a replacement well for TW-8, was drilled 75 m (246 ft) west of TW-8 does not contain tritium (Figure D-2.2-19[l]). Concentrations of tritium are slightly above the IDL of 0.29 pCi/L, using electrolytic enrichment, at R-1 and R-14 (screen 1) (Figures D-2.2-19[l] and D-2.2-21[l]). Concentrations of tritium are less than analytical detection at wells R-13, R-14 (screen 2), R-33, and R-34 (Figures D-2.2-20[l], D-2.2-21[l], D-2.2-24[l], D-2.2-25[l]).

Strontium-90

Strontium-90 has a half-life of 28.78 y and decays to yttrium-90 through emission of a beta particle. Strontium-90 reversibly adsorbs onto sediments containing clay minerals through cation exchange reactions (Langmuir 1997, 56037). Strontium is stable in the +II oxidation state in aqueous solution. Strontium forms complexes with bicarbonate ($SrHCO_3^+$, $SrCO_3^0$) under near-neutral pH conditions. Cationic forms of strontium are considered to be less mobile than neutral forms under alkaline pH conditions because cation exchange dominates over anion exchange (Langmuir 1997, 56037). Stable or natural strontium and strontium-90 precipitates from solution as $SrCO_3$ (strontianite), which has an aqueous solubility of $10^{-9.27}$ moles/L (6.63×10^6 pCi/L) (Langmuir 1997, 56037). Therefore, precipitation is another potential process for removing strontium-90 from solution. Surface water and groundwater have much higher concentrations of stable strontium than of strontium-90, which enhances precipitation of $SrCO_3$ within the watershed for long periods of time exceeding 30 years.

Strontium-90 in Surface Water and Alluvial Groundwater

The spatial trends of current (2000 through 2005) strontium-90 concentrations in both nonfiltered and filtered surface water and alluvial groundwater samples are shown in box plots in Appendix D, Figures

D-2.1-31 through D-2.1-33. These plots indicate that the TA-50 RLWTF outfall and former discharges from the TA-35 WWTP are important Laboratory sources of strontium-90 within the Mortandad watershed. Dissolved strontium-90 makes up approximately 50% to 90% of total strontium-90 within surface water and alluvial groundwater in the Mortandad watershed, suggesting that this radionuclide reversibly adsorbs onto sediments through cation exchange reactions. In Mortandad Canyon, concentrations of strontium-90 are generally higher in surface water at location E200 east of the confluence with Effluent Canyon and in reach M-2E and in alluvial water in the segment of Mortandad Canyon between wells MCO-3/MCA-5 and MCO-6 (Figure D-2.1-32). In Effluent Canyon, concentrations in surface and alluvial groundwater are elevated east of the RLWTF outfall, which is clearly a source of strontium-90 to the watershed. The maximum concentration of strontium-90 in surface water is approximately 48 pCi/L measured in surface water in Mortandad Canyon at location E200. The highest concentration of strontium-90 was 81.6 pCi/L at MCO-5, the alluvial groundwater monitoring well located east of the PRB and west of the confluence with Ten Site Canyon (Figure D-2.1-32). Concentrations of total strontium-90 sharply decrease downcanyon to less than 4 pCi/L at alluvial well MCO-7 and other wells farther to the east. Groundwater mixing and/or an increase in the adsorptive capacity of the alluvium (silt-sized material) may explain concentration decreases of strontium-90 between alluvial wells MCO-6 and MCO-7. Persistent surface water was uncommon in this portion of the Mortandad watershed during the investigation period; therefore, contamination was generally limited to alluvial groundwater.

The spatial distribution of strontium-90 concentrations in surface water in Ten Site Canyon above the Mortandad Canyon confluence indicate that the bulk of strontium-90 has migrated downcanyon to reach TS-2E (Figure D-2.1.33). The highest concentration of total strontium-90 within this reach is 21.3 pCi/L. A portion of the strontium-90 released from TA-35 WWTP, however, occurs in upper Ten Site Canyon in surface water within reach TS-1C with a maximum concentration of 7 pCi/L.

Figure 7.2-29 is a time series plot for strontium-90 covering the period 1963 through 2005. It shows the annual strontium-90 concentration in RLWTF effluent and the concurrent concentrations at alluvial wells MCO-3/MCA-5, MCO-5, MCO-6, MCO-7, and MCO-7.5. The strontium-90 concentrations in the outfall averaged 380 pCi/L from 1963 to 1989, with a maximum concentration of 1725 pCi/L. During this same period, strontium-90 concentrations in the alluvial wells were elevated with many measurements over the MCL of 8 pCi/L. Concentrations at the alluvial wells that are located closest to the TA-50 outfall, MCO-3 and MCO-5, tend to rise in response to outfall releases. Those wells farther downcanyon, MCO-7 and MCO-7.5, have relatively constant, low concentrations of strontium-90. It is likely that adsorption onto various adsorptive phases within alluvial sediments retards further strontium-90 transport. After 1993, outfall concentrations dropped below 10 pCi/L, and from 2000 to 2004, the average outfall concentration has been less than 4 pCi/L due to source reduction implemented by the waste generators before entering the TA-50 RLWTF and through cation exchange and/or reverse osmosis treatment at the facility. Correspondingly, concentrations in the alluvial wells have declined. The rate of decline of strontium-90 concentrations in alluvial groundwater is controlled by concentration decreases in the TA-50 effluent, by cation exchange and dilution in the environment, and by radioactive decay.

Figure 7.2-30 shows the alluvial aquifer response to strontium-90 source reduction for the period 2000 through 2005, when outfall concentrations dropped to below 4 pCi/L. This response is not similar to that observed for nitrate, perchlorate, or tritium, which showed a lag in dilution at alluvial wells located farther from the source. Here the more distal wells (MCO-7 and MCO-7.5) maintain low concentrations because they were not elevated in the first place. Concentrations at wells MCO-3/MCA-5, MCO-5, and MCO-6 are slowly declining in response to the source reduction. This response may be delayed by desorption of strontium-90 from the sediment and alluvial load.

Strontium-90 in Vadose-Zone Pore Water, Perched-Intermediate Groundwater, and the Regional Aquifer

Plots of concentration versus depth for strontium-90, shown in Figures D-2.4-22 through D-2.4-38, indicate that this radionuclide is concentrated within the alluvium and at the alluvium/bedrock contact. Higher concentrations of strontium-90 are observed in alluvial groundwater indicating that a fraction of this radionuclide adsorbs onto alluvial material, as discussed above. Strontium-90 was detected in core samples collected at MCB-5, MCB -6, MCB-7, and R-1 at depths less than 11 m (35 ft). The maximum concentration of strontium-90 is approximately 1.16 pCi/g measured at borehole MCB-5 at a depth of 6 m (20 ft) within the alluvium. The strontium-90 values shown in these plots are generally below the analytic detection limit, as indicated by the open blue triangles. Concentrations of strontium-90 in core samples were less than analytical detection at MCB-1, MCB-2, MCB-8, MCB-9, MCB-10, MCB-11, MCB-12, MCB-14, MCB-15, MCB-16, R-14, R-15, and R-28. Strontium-90 is not consistently detected within perched-intermediate zones and the regional aquifer within the Mortandad watershed due to its ability to adsorb onto silt- and clay-sized material present within the alluvium and weathered Bandelier Tuff.

Plutonium-238 and Plutonium-239,240

The half-life of plutonium-238 is 87.7 yr, and the isotope decays to uranium-234 by emission of an alpha particle (Parrington et al. 1996, 58682). The half-lives of plutonium-239 and plutonium-240 are 2.410×10^4 and 6.56×10^3 yr, respectively, and they decay to uranium-235 and uranium-236, respectively, by emission of alpha particles (Parrington et al. 1996, 58682). Plutonium strongly adsorbs onto sediments containing clay minerals and ferric (oxy)hydroxides (Langmuir 1997, 56037) through surface complexation reactions. Plutonium is stable in the +III, +IV, +V, and +VI oxidation states in aqueous solution. Plutonium(III, V, and VI) forms complexes with bicarbonate (for example, near pH 7, $PuCO_3^+$, $PuO_2CO_3^-$, $PuO_2(CO_3)_2^{2-}$, and $PuO_2CO_3^0$). Plutonium(IV and V) hydrolyzes to form $Pu(OH)_4^0$ and PuO_2^+. Plutonium(V and VI) complexes are considered to be the most stable in oxidizing surface water and alluvial groundwater within the Mortandad watershed based on the co-occurrence of nitrate, perchlorate, chromium(III, VI), and solid organic matter in the sediments. Cationic forms of complexed plutonium are considered to be less mobile than anionic forms under alkaline pH conditions because most adsorbents tend to have net-negative surface charges (Langmuir 1997, 56037). Plutonium(IV) oxide, consisting of plutonium-239, is characterized by low aqueous solubility of $10^{-35.38}$ moles/L ($6.15 \times 1\ 0^{-23}$ pCi/L) at pH 7, calculated using thermodynamic data cited in Langmuir 1997 (56037); therefore, precipitation from the aqueous phase provides another potential process for removing plutonium from solution.

Plutonium-238 and -239 in Surface Water and Alluvial Groundwater

The spatial trends in plutonium-238 and plutonium-239 concentrations in surface water and alluvial groundwater from 2000–2005 are shown in box plots for different portions of the Mortandad watershed in Appendix D, Figures D-2.1-34 through D-2.1-36 and Figures D-2.1-37 through D-2.1-39, respectively. Detections of plutonium-238 and plutonium-239,240 occur in both filtered and nonfiltered samples throughout the Mortandad watershed, but the highest concentrations are from nonfiltered surface water samples, indicating the preference for plutonium to adsorb to fine-grained sediment and solid organic matter and the presence of plutonium-contaminated suspended solids in the samples.

The distributions of detected values of plutonium-238 and plutonium-239,240 are attributed to two primary sources: the TA-50 RLWTF outfall and the former TA-35 WWTP outfall (Section 2.1). In Mortandad Canyon, the highest frequency of detected plutonium-238 and plutonium-239 concentrations occurs in surface water immediately east of the TA-50 outfall within reach E-1E and below the Mortandad

confluence at gage E200. The concentrations and frequency of detection decrease immediately downcanyon. From monitoring well MCO-3/MCA-5 down Mortandad Canyon, only scattered detected concentrations occur in surface water and alluvial groundwater. Overall, a higher frequency of detection occurs in nonfiltered samples, indicating the presence of plutonium-contaminated suspended solids in the samples.

In Ten Site Canyon, above the confluence with Pratt Canyon, plutonium-238 was detected in filtered and nonfiltered surface water samples within reaches TS-1C and TS-1E with maximum detected concentrations of 0.234 and 1.79 pCi/L, respectively (Figures D-2.1-33 and D-2.1-36). Maximum concentrations of plutonium-239 detected in filtered and nonfiltered surface water samples were 0.0712 and 0.79 pCi/L, respectively, in the same reaches (Figures D-2.1-36 and D-2.1-39). Concentrations of both plutonium-238 and plutonium-239 are less than detection east of reach TS-1C within Ten Site Canyon. The limited concentrations of plutonium detected in surface water in reach TS-1C are probably related to the presence of plutonium-contaminated sediments redistributed downcanyon from the TA-35 sources (Section 7.1).

Appendix D, Section D-2.2, shows a time series plot for plutonium-238 and plutonium-239 covering the period 1963 through 2005 for surface water gage E200 and the entire series of alluvial wells. These plots show the highest concentrations of plutonium occurred just downstream of the TA-50 outfall in surface water at gage E200 and in alluvial groundwater in well MCO-3. Concentrations decline rapidly down canyon because of adsorption of plutonium onto sediments and alluvial deposits. Maximum plutonium concentrations in surface and alluvial groundwater occurred during the 1980s when releases were highest (Table 2.1-1). Surface water and alluvial groundwater concentrations of plutonium-238 and plutonium-239 are currently both less than 7 pCi/L in nonfiltered samples and less than 2.5 pCi/L in filtered samples.

Plutonium-239,240 in Vadose-Zone Pore Water, Perched-Intermediate Groundwater, and the Regional Aquifer

Figures D-2.4-22 through D-2.4-38 show the distribution of plutonium-239 concentrations in core samples collected from Mortandad Canyon and Ten Site Canyon. Both plutonium and americium adsorb onto solid surfaces, and these two actinides are generally collocated in the core samples, although plutonium was detected at a higher frequency in samples at depth. Plutonium-239 was detected in core holes MCB-5, MCB-6, MCB-7, MCB-9, MCB--10, R-1, and R-14. Plutonium-239 was detected at a concentration of 0.03 pCi/g at a maximum depth of 61 m (200 ft) within the Cerro Toledo interval at R-14. This occurrence could be attributed to translocation or downward movement during coring operations at R-14. The maximum concentration of plutonium-239 was 1.16 pCi/g measured at core hole MCB-7 at a depth of 3 m (10 ft) within the alluvium. Several samples from MCB-5, MCB-7, MCB-9, and MCB-10, contained detectable plutonium-239 at depths suggesting that colloid transport under saturated and unsaturated flow conditions has taken place. Plutonium-239 was not detected at core holes MCB-1, MCB-2, MCB-8, MCB-11, MCB-12, MCB-15, MCB-16, R-14, R-15, and R-28.

Plutonium-239,240 is not frequently detected within perched-intermediate zones and the regional aquifer within the Mortandad watershed due to its ability to strongly adsorb onto silt- and clay-sized material present within stream channels, alluvium, and weathered Bandelier Tuff. Possible detections of plutonium-239, 240 within deep saturated zones occur in nonfiltered samples, and transport mechanisms may include adsorption onto colloids migrating through fractured media.

Americium-241

Americium-21 has a half-life of 432.7 yr and decays to neptunium-237 through emission of an alpha particle. Americium is stable in the +III oxidation state in aqueous solution (Langmuir 1997, 56037). Americium-241 very strongly adsorbs onto sediments containing clay minerals and ferric (oxy)hydroxide, through cation exchange and surface complexation reactions (Langmuir 1997, 56037). Americium forms complexes with bicarbonate. At pH 7, it is stable as $AmCO_3^+$ at a partial pressure of CO_2 gas = 10^{-2} bar, typical of groundwater. Under surface water conditions with a partial pressure of CO_2 gas = $10^{-3.5}$ bar, americium is mainly stable as $AmOH^{2+}$ at pH 7 (Langmuir 1997, 56037). Americium-241 precipitates from solution as $AmOHCO_3$, and its solubility minimum is $10^{-8.7}$moles/L (1.64×10^6 pCi/L) at pH 8.3. Adsorption of americium-241 onto clay minerals and ferric (oxy)hydroxide is the dominant process taking place in the watershed for removing this actinide from solution.

Americium-241 in Surface Water and Alluvial Groundwater

The spatial trends in americium-241 concentrations in surface water and alluvial groundwater from 2000 to 2005 are shown in box plots for different portions of the Mortandad watershed in Appendix D, Figures D-2.1-40 through D-2.1-42. The release history of americium-241 from the TA-50 RLWTF is similar to that of plutonium-239,240, even though less americium-241 was released in comparison to plutonium-239,240 (Table 2.1-1 and LANL 1997, 56835). The spatial distribution of americium-241 in water is similar to plutonium-239 in that highest concentrations detected in water are near the TA-50 source, and the concentrations and frequency of detection decrease rapidly downcanyon (Figures D-2.1-40 through D-2.1-41). In Effluent Canyon, the highest frequency of detected americium-241 concentrations occurs in surface water in reach E-1E below the TA-50 outfall and at gage E200 immediately east of the confluence with Mortandad Canyon. From monitoring well MCO-3/MCA-5 down Mortandad Canyon, detected concentrations occur in surface water and alluvial groundwater. Overall, a higher frequency of detection occurs in nonfiltered samples, indicating the presence of americium-contaminated suspended solids in the samples.

A smaller source of americium-241 occurred at the TA-35 WWTP. In Ten Site Canyon, americium-241 is identified in surface water only within reach TS-1C at a maximum total concentration of 0.2 pCi/L (Figure D-2.1-42). The concentrations of americium-241 detected in water in Ten Site Canyon are probably related to the presence of americium-contaminated sediments redistributed down canyon of the TA-35 source.

Appendix D, Section D-2.2, shows time series plot for americium-241 covering the period 1963 through 2005 for surface water gage E200 and the entire series of alluvial wells. The trend shown in these plots is very similar to that for plutonium in that the highest concentrations of americium occurred just downstream of the TA-50 outfall in surface water at gage E200 and in alluvial groundwater in well MCO-3. Concentrations decline rapidly downcanyon because of adsorption onto sediments and alluvial deposits. Recent nonfiltered samples show that surface water concentrations are less than 15 pCi/L, and alluvial groundwater concentrations are less than 5 pCi/L at MCO-3 and decline rapidly downcanyon from there.

Americium-241 in Vadose-Zone Pore Water, Perched-Intermediate Groundwater, and the Regional Aquifer

Figures D-2.4-22 through D-2.4-38 show the distribution of americium-241 concentrations in core samples with depth collected at the MCB holes in Mortandad Canyon. Americium-241 was infrequently detected in core samples collected at MCB-5, -6, -7, -8, and -14. This actinide was detected (0.04 pCi/g) at a maximum depth of 68.6 m (225 ft) within the Bandelier Tuff at MCB-14. This occurrence could be

attributed to translocation or downward movement during coring operations at MCB-14. Detectable concentrations of americium-241 typically occurred at depths less than 9.1 m (30 ft) within the alluvium due to its strong affinity for ferric (oxy)hydroxide and clay minerals. Core hole MCB-8 contained one detect of americium-241 at a depth of 27 m (90 ft), which may have resulted from coring operations. Core hole MCB-14 contained detectable concentrations of americium-241 at 12 and 21 m (40 and 70 ft) within the alluvium and at the contact of the alluvium-Cerro Toledo interval, respectively. The maximum concentration of americium 241 was approximately 1.05 pCi/g measured at core hole MCB-7 at a depth of 3 m (10 ft) within the alluvium. Americium-241 was not detected in samples collected from core holes MCB-1, MCB-2, MCB-9, MCB-10, MCB-11, MCB-12, MCB -13, MCB-15, and MCB-16.

Americium-241 is not consistently detected within perched-intermediate zones and the regional aquifer (see Appendix D, Section D-2.2) within the Mortandad watershed due to its ability to strongly adsorb onto silt- and clay-sized material present within the alluvium and weathered Bandelier Tuff. Possible detections of americium-241 within deep saturated zones occur in nonfiltered samples and transport mechanisms may include adsorption onto colloids migrating through fractured media.

7.3 Summary of Physical System Conceptual Model

This section summarizes the main elements of the physical system conceptual model whose individual elements were discussed in more detail in Sections 7.1 and 7.2. The primary focus of this section is the fate and transport of contaminants released from the TA-50 RLWTF because it is identified as the main source of contaminants in the Mortandad watershed. Other significant sources such as TA-35 and TA-48 are discussed at length in Sections 7.1 and 7.2, and the conceptual model discussed below also applies to the fate and transport of contaminants from these sources. Figure 7.0-1 illustrates key aspects of the physical system conceptual model.

Most contaminants in the Mortandad watershed are derived from Laboratory sources that released wastewater from outfalls into tributary drainages of Mortandad Canyon. Contaminants include radionuclides, inorganic chemicals, and organic chemicals as detailed in Sections 7.1 and 7.2. The mobility of contaminants is controlled by the geochemical characteristics of each contaminant and the geochemical properties of the medium along transport pathways (aqueous solubility, speciation, oxidation/reduction, precipitation/dissolution, adsorption/desorption, microbial and mineralogical characteristics of sediments and aquifer material). The nature and volume of effluent released from outfalls varied over time as a result of changes in research activities at the Laboratory, changes in wastewater treatment methods, and changes in environmental standards. As a result, the present-day distribution of contaminants in the watershed reflects the geochemical properties of individual contaminants, the complex history of releases from multiple Laboratory sites, and hydrological and mineralogical properties of aquifer material. Redistribution of contaminants by surface water, sediment transport, and groundwater is an ongoing process within the Mortandad watershed.

Initially, contaminants are transported from their release sites dissolved in water or adsorbed onto sediment particles and solid organic material. Some contaminants are deposited in soils between outfalls and stream channels, but most are transported down tributary drainages into the main canyon system by surface-water flow and sediment transport. Once adsorbed onto sediment particles in the streambed, contaminants are redistributed by floods that scour the streambed and mobilize the bed sediment. Contaminants associated with coarse-size fractions (coarse sand and coarser) are generally transported as bed load along the streambed, whereas contaminants associated with fine-size fractions (fine sand and finer) are generally transported in suspension. These include cesium-137, americium-241, plutonium-238, plutonium-239,240, chromium(III), lead, mercury, and PCBs. Contaminants are generally collocated in the sediment deposits, primarily occurring in post-1942 sediment deposits and preferentially

occurring in fine rather than coarse facies sediment. During floods, sediment from a variety of sources, much of it not contaminated, is mixed, changing contaminant concentrations longitudinally along the channel. The net result is a general downcanyon decrease in contaminant concentrations in sediment with distance from a contaminant source area (Figure 7.0-1). In general, the inventory of contaminants in sediments increases in downcanyon areas, primarily because post-1942 sediment accumulated in thicker and more extensive deposits where the canyon floor widens eastward. Most of the contaminant inventory in Mortandad Canyon occurs in reach M-3E, upcanyon from the Ten Site Canyon confluence. A notable exception to this trend is the deposition of chromium in Effluent Canyon close to its release site at TA-48.

In Effluent Canyon, the transport of contaminants by surface water is facilitated where thin alluvium overlies relatively impermeable bedrock in the stream channel; this limits the amount of infiltration along the stream channel and results in greater movement of surface water downcanyon. The downcanyon extent of surface water flow varies with effluent discharge rates, runoff from storm events and snowmelt, and prior moisture conditions along the channel. In Mortandad Canyon below the Effluent Canyon confluence, surface water infiltrates the Mortandad Canyon channel where the alluvium thickens and groundwater storage capacity increases (Figure 7.0-1). The maximum extent of persistent surface water occurred in the 1960s to early 1970s when effluent discharge volumes were highest. During this time, surface flow generally extended about 1.5 km (1 mi) or less downcanyon from the TA-50 RLWTF outfall. Discharge volume from the TA-50 RLWTF outfall has progressively decreased since the early 1980s, and today persistent surface water flow generally extends only about 600 m (1970 ft) below the Effluent Canyon confluence (Figure 7.0-1). Runoff from storm events and snowmelt sometimes causes ephemeral flow and episodic infiltration to occur as far east as the sediments traps (and rarely farther downcanyon), but these events are infrequent. Contaminant concentrations in surface water have decreased over time in response to improved treatment technologies employed at the TA-50 RLWTF, especially since 2000.

Infiltration of surface water in the stream channel recharges alluvium within the watershed. Stable isotope data suggest that some surface water and shallow subsurface moisture is lost through evapotranspiration. The remaining water recharges alluvial groundwater that generally accumulates in the lower part of the alluvial deposits, most often perching on weathered bedrock units. Perched alluvial groundwater is a major pathway for the downcanyon transport of soluble contaminants. In Mortandad Canyon, the thickest and most persistent perched alluvial groundwater occurs between MCB-5, where the canyon begins to widen eastward to MCB-11 located east of the sediment traps (Figure 7.0-1). Alluvial groundwater occurs on an intermittent basis as far east as alluvial well MT-4 (Figure 3.2-1). Well hydrographs suggest that the alluvial groundwater levels respond relatively quickly to precipitation events in areas closest to zones of surface water infiltration and that significant lag times may occur at the eastern limit of alluvial saturation. These data support the interpretation that the alluvial groundwater system is recharged by infiltration of persistent and intermittent surface water in gradually thickening alluvium west of MCB-5 and that underflow within the alluvium is the dominant recharge process for alluvial groundwater farther down canyon. Saturation is not uniformly distributed within the alluvium, and in some cases, dry boreholes were drilled next to a location or well where alluvial groundwater was encountered. Similarly, hydrographs for adjacent alluvial wells frequently respond at different times to precipitation events and runoff events. These observations suggest that alluvial groundwater flows along preferential pathways within the highly heterogeneous alluvium and that the aquifer may resemble a network of cross-connected channels rather than a continuous zone of saturation at the base of alluvium. Contaminant concentrations in alluvial groundwater have decreased over time in response to improved treatment of effluent at the TA-50 RLWTF. Concentrations in alluvial groundwater currently account for an estimated 0.1% of the nitrate mass and 2.8% of the perchlorate mass in the watershed. Although overall concentrations are declining, there is a trend of increasing concentration for mobile constituents downcanyon from well MCO-5 to approximately well MCO-7.5 (Figure 3.2-1). This trend is indicative of a lag in the response of alluvial groundwater to the application of improved effluent treatment technologies.

The lag is related in part to distance from the outfall, but increasing alluvial storage from west to east is probably a more important factor. Concentrations at more distal locations will continue to decline in response to lower effluent concentrations and to further dilution by runoff events.

Deeper infiltration of alluvial groundwater into bedrock units results in the vertical transport of contaminants into the suballuvium vadose zone. Transport of contaminants to these deeper zones is generally limited to soluble constituents such as nitrate, perchlorate, fluoride, tritium, sulfate, and chromium(VI). Contaminant profiles from core holes indicate that maximum contaminant concentrations of these mobile constituents and most of the contaminant mass (an estimated 96.6% of the nitrate mass and 94.6% of the perchlorate mass) occurs in bedrock units in the upper half of the vadose zone in the region extending from MCB-5 on the west to MCOBT.8.5 on the east (Figure 7.0-1). The Otowi Member of the Bandelier Tuff accounts for an estimated 55.8% of the nitrate mass and 67.7% of the perchlorate mass in Mortandad Canyon. The western extent of vadose-zone contamination is poorly constrained because Mortandad Canyon is inaccessible to drilling between the Effluent Canyon confluence and MCB-5. Thinning of alluvium over less permeable tuffs 500 to 1000 m (1640 to 3280 ft) west of MCB-5 probably controls the western limit of significant alluvial groundwater infiltration. The eastern extent of vadose-zone contamination is constrained by core hole data from MCOBT-8.5 and R-28. The greatest mass of contamination in the vadose zone occurs beneath the portion of the canyon that contains the thickest and most persistent alluvial groundwater. Bedrock units such as Tshirege unit Qbt 1g, the Cerro Toledo interval, and the Otowi Member underlie the alluvium in this area, and because of their porous nature, alluvial groundwater is able to percolate through these units. Moisture associated with vadose-zone contamination is elevated relative to other parts of the canyon, but the rocks are generally not fully saturated. Movement of moisture and contaminants probably occurs as gravity-driven porous flow. Estimates of vertical transport velocities of nitrate based on a release of unique isotopically light nitrogen from October 1986 to September 1989 range between 2.5 and 2.9 m/y (8.2 and 9.5 ft/y). Estimates of transport rates based on peak tritium releases to the canyon suggest that vertical transport rates have declined substantially from about 11 m/yr (36.1 ft/y) in the late 1970s to about 1.36 m/yr (4.46 ft/y) today. Finally, calibration to nitrate profiles in R-15 and MCOBT-8.5 yield approximate transport velocities of 6 m/yr (20 ft/yr) in 1968 to 1.2 m/yr (4 ft/yr) in 2002. These studies apply to mobile constituents and indicate vadose-zone transport velocities were greater in the past and that over time, transport velocities decreased as discharges to the watershed from outfalls declined. Adsorbing constituents have much slower transport rates and are generally not present within the suballuvium vadose zone.

A thin zone (<1m [<3 ft]) of perched-intermediate groundwater occurs within the clay-rich basaltic rubble at the top of the Cerros del Rio basalt near the Mortandad–Ten Site Canyon confluence (Figure 7.0-1). A thicker zone (up to 21.9 m [72 ft]) of perched saturation occurs near the base of the Cerros del Rio basalt near R-15. These perched-intermediate zones probably represent two unrelated groundwater bodies of limited lateral extent along the canyon axis (Figure 7.0-1). Based on the distribution of boreholes encountering perched-intermediate groundwater, the lateral extent of these groundwater bodies is probably less than 450 m (1500 ft). Contaminant concentrations within these perched zones show increasing trends over time, indicating that limited masses of the most mobile constituents (nitrate, perchlorate, chromium(VI), and tritium) have migrated from upgradient areas through the vadose zone along preferential pathways. Concentrations in perched-intermediate groundwater currently account for only an estimated 0.10% of the nitrate mass and 1.6% of the perchlorate mass in Mortandad Canyon. Perched-intermediate groundwater percolates into the Puye Formation, resulting in further vertical transport of contaminants into the lower vadose zone (Figure 7.0-1). Mobile constituents percolate through the lower vadose zone, reaching the regional water table.

The water table of the regional aquifer lies approximately 300 m (984 ft) below the canyon floor in Mortandad Canyon (Figure 7.0-1). The regional aquifer is a complex, heterogeneous system that includes

confined and unconfined zones. Hydraulic communication between these zones is uncertain and spatially variable. The shallow portion of the regional aquifer (along the water table) is predominantly under phreatic (unconfined) conditions and has limited thickness (approximately 30–50 m [98–164 ft]). The groundwater flow and transport directions in this zone generally follow the gradient of the regional water table; the flow is east/southeast toward White Rock Canyon springs and the Rio Grande. The shape of the regional water table is predominantly controlled by areas of regional recharge (Sierra de los Valles and some Pajarito Plateau canyons) and discharge (White Rock Canyon springs and the Rio Grande). The deep portion of the regional aquifer is predominantly under confined conditions, and it is heavily stressed by Pajarito Plateau water-supply pumping. The pumping likely has a small impact on the flow directions in the phreatic zone because of poor hydraulic communication (cf. Appendix O). Capture of contaminants by supply well PM-3 seems unlikely because of this poor vertical hydraulic communication. However, the poor hydraulic communication does not preclude the possibility that some contaminant migration may occur between the shallow and deep zones. Between the two zones, the hydraulic gradient has a substantial vertical component due to water-supply pumping, creating the possibility that downward contaminant flow may occur along hydraulic windows and possibly along filter packs in water-supply wells. However, upward vertical gradients near PM-3 might provide natural protection against entry of contaminants from the phreatic zone into the well screen. Mobile contaminants, including nitrate, perchlorate, chromium(VI), and tritium, are observed only in the shallow zone of the regional aquifer beneath the Mortandad watershed. Some wells, such as R-15 and R-28, show increasing contaminant concentrations over time, suggesting breakthrough of mobile constituents from the vadose zone is increasing over time. Differences in nitrate isotopic ratios for some wells (e.g., R-28 vs. R-15) indicate that contamination in regional groundwater beneath Mortandad Canyon includes contributions from mixed source areas. The future pathways of contaminant movement from these locations should follow the groundwater flow direction along the regional water table. The contaminant flow should be to the east without substantial temporal changes due to seasonal effects.

8.0 RISK ASSESSMENTS

This section presents the methods used to evaluate the potential for adverse ecological and human health risks from COPCs in sediment and surface water. Risk characterization results, uncertainty analysis, and risk assessment summary are also provided for each assessment.

8.1 Baseline Ecological Risk Assessment

Biological data were collected in the Mortandad watershed to evaluate the potential for adverse ecological effects from contaminants in sediment and persistent surface water. A biological investigation work plan was developed based on the application of the eight-step EPA ecological risk assessment guidance for Superfund (ERAGS) (EPA 1997, 59370) to COPECs in sediment and persistent surface water (LANL 2005, 89308).

Steps 1 and 2 of ERAGS include the screening-level ecological risk assessment (SLERA) (LANL 2004, 87630), which identifies COPECs and ecological receptors potentially at risk. Ecological screening results based on the comparison of ecological screening levels (ESLs) with available sediment and water data are provided in the “Mortandad Canyon Biota Investigation Work Plan” (LANL 2005, 89308) and in Appendix E-1. Also presented in the biota investigation work plan is a comparison of available data with DOE biota concentration guidelines (BCGs) for radionuclides (DOE 2002, 85637; DOE 2004, 85639). These screening-level assessments identified COPECs and formed the basis for proceeding to the baseline ecological risk assessment (ERAGS Steps 3 to 8).

Steps 3 and 4 of ERAGS comprise problem formulation and study design, which include refining the list of COPECs, developing a conceptual exposure model, selecting assessment endpoints, and selecting associated measures of effect and exposure. The study design required for these measures was included in the biota investigation work plan (LANL 2005, 89308). Aspects of study design were modified based on field verification of the design (ERAGS Step 5) and on comments received from NMED (NMED 2005, 92084). Deviations to the original biota work plan are discussed in Section 8.1.2. ERAGS Steps 6 and 7 comprise the implementation of the study design, analysis of ecological exposure and effects, and risk characterization. ERAGS Step 8 is risk management and the conclusions that may lead to risk management activities are documented in Section 9.

8.1.1 Problem Formulation

This section addresses the baseline ecological risk assessment problem formulation, which is Step 3 of ERAGS. A problem formulation was presented in Appendix D of the "Mortandad Canyon Biota Investigation Work Plan" (LANL 2005, 89308, pp. D-1–D-3). Problem formulation includes refinement of the list of COPECs, a literature search on known ecological effects, the conceptual exposure model, and the selection of assessment endpoints. Additional samples have been collected since the initial problem formulation in the biota investigation work plan, and new COPECs have been identified; therefore the problem formulation elements are updated and presented in the following sections.

8.1.1.1 Refinement of COPEC list

The third step of the ERAGS process involves refinement of the COPEC list from the screening to focus on those COPECs that have the largest impact on the potential ecological risk. As explained in the SLERA methods document (LANL 2004, 87630, p. 31), the criterion for retaining a COPC as a COPEC is a HQ greater than 0.3. The ESL screening excludes only COPCs with an HQ less than or equal to 0.3, which are COPCs for which no potential for ecological risk exists. To determine whether areas of the canyon may pose a risk to ecological receptors, and therefore what areas should be included within the scope of the biota investigation, the criterion of an HQ greater than 3 was used. An HQ greater than 3 represents levels that may impact receptors and is therefore appropriate for determining which COPECs should be included in site-specific biota studies in the Mortandad watershed. This criterion of 3 is based on the geometric mean of the ratio between the no observed adverse effect level (NOAEL) and the lowest observed adverse effect level (LOAEL) (Dourson and Stara 1983, 73474). Concentrations corresponding to LOAELs represent levels where impacts to individuals or populations may occur, and these levels represent a more appropriate criterion for determining which COPECs should be included in site-specific biota analyses to assess if impacts to ecological receptors have actually occurred. The same criterion of an HQ greater than 3 was used to refine the list of COPECs for the baseline studies conducted in Los Alamos and Pueblo Canyons (LANL 2004, 87390, p. 8-2). Receptors representing threatened and endangered (T&E) species are evaluated versus an HQ greater than 1 to ensure protection of each individual within the population.

Selection of study design COPECs for soil was based on comparison of the maximum detected concentrations in all geomorphic units within a reach with the minimum soil ESL. Active channel sediments may be exposed due to the transient nature of water flow in the channels in this watershed; therefore concentrations in the active channel geomorphic unit (c1) were included in the screening for terrestrial receptors. The COPECs for soil identified in the biota investigation work plan are: arsenic, barium, cadmium, chromium, copper, total cyanide, lead, manganese, mercury, selenium, silver, thallium, vanadium, zinc, americium-241, cesium-137, plutonium-238, plutonium-239, strontium-90, Aroclor-1254, Aroclor-1260, acenaphthene, chrysene, naphthalene, di-n-butyl phthalate, and endrin aldehyde (LANL 2005, 89308). Study design COPECs for sediment were chosen based on a comparison of maximum

detected concentrations in geomorphic unit c1 (the active channel sediments) with the ESLs for sediment. The study design COPECs in sediment identified in the biota investigation work plan include: aluminum, arsenic, barium, copper, mercury, silver, vanadium, acenaphthene, acetone, anthracene, Aroclor-1260, benz(a)anthracene, benzo(a)pyrene, benzo(b)fluoranthene, benzo(g,h,i)perylene, benzo(k)fluoranthene, alpha-chlordane, gamma-chlordane, chrysene, 4,4-DDT, di-n-butylphthalate, dibenz(a,h) anthracene, fluoranthene, fluorene, indeno(1,2,3-c,d)pyrene, 4,4'-methoxychlor, 2-methylnaphthalene, naphthalene, phenanthrene, and pyrene. Study design COPECs for water were based on the comparison to ESLs and DOE BCGs. Study design COPECs for water identified in the biota investigation work plan are: aluminum, barium, cadmium, copper, cyanide (total), lead, manganese, silver, zinc, americium-241, and radium-226.

After its review of the biota investigation work plan, NMED requested considering gross alpha and selenium as COPECs in all evaluations (NMED 2005, 92084). There is no ESL for gross alpha, but gross alpha has an NMED surface water standard in 20.6.4 NMAC. Therefore, gross alpha was evaluated through screening of surface water against this standard. Individual alpha-emitting radionuclides were screened against the ESLs and DOE BCGs for each individual radionuclide. In the screening conducted for the biota investigation work plan (LANL 2005, 89308), selenium was designated as a study design COPEC only for plants. In response to NMED's concerns the evaluation of the results of each field study and the modeling of COPEC ingestion through the food chain to avian and mammalian receptors includes selenium.

Subsequent to the screening against minimum ESLs, the study design COPECs were screened against the ESLs for individual receptors to determine which COPECs should be addressed by each of the field measures. Table D-6.0-1 of the biota investigation work plan (LANL 2005, 89308) lists the COPECs for individual receptors; these subsets of COPECs were used to determine the appropriate analytical suites and locations for each measure. The COPECs and analytical suites associated with each measure are described in the discussion of each individual field measure in Section 8.1.2. The receptors potentially at risk from exposure to soil COPECs include plants, soil invertebrates (earthworms), small mammals, mammalian carnivores, omnivorous birds, and carnivorous birds representing a T&E species, the Mexican spotted owl (*Strix occidentalis lucida*). Receptors at potential risk from exposure to sediment include the swallow (which also represents a T&E species, the southwestern willow flycatcher [*Empidonax traillii extimus*]), the bat, and the aquatic community (which represents a number of aquatic species). Receptors at potential risk from exposure to COPCs in water also included representatives of the aquatic community (aquatic invertebrates and algae).

Screening Against ESLs and BCGs for 2005 Sediment and Water Data

Sediment samples were collected in 20 of the investigation reaches in the Mortandad watershed and in the background reach in Los Alamos Canyon in 2005 after preparation of the biota investigation work plan. The concentrations of COPCs in these samples were screened against ESLs and BCGs to determine if any new study design COPECs (COPECs with an HQ >3) were identified by the additional sampling. Screening the data from 2005 samples was conducted with ECORISK Database Version 2.2 (LANL 2005, 90032); the screening documented in the "Mortandad Canyon Biota Investigation Work Plan" (LANL 2005, 89308) used the version of the ESL database that was current at the time that the report was written, ECORISK Database Version 2.1 (LANL 2004, 87386). The tables for this screening are presented in Section E-1.2 of Appendix E. The section below includes a discussion of the results of the screening and whether new COPECs were identified based on higher detected maximum concentrations or a decrease in the ESL between the versions of the database.

Additional COPECs for Soil

Tables E-1.2-1 to E-1.2-3 in Appendix E show the HQs for soil COPECs based on the screening of the 2005 samples. The maximum detected concentrations of analytes in soil for these samples are available in the data files in Appendix C.

Soil samples from two reaches with the highest concentrations of chromium were analyzed for hexavalent chromium in 2005. n reach E-1FW, the HQ for both the earthworm and the plant for hexavalent chromium was 5.8. Based on other study design COPECs, reach E-1FW was already included in the plant and earthworm toxicity studies that includes metals; therefore, no additional studies are necessary based on the designation of hexavalent chromium as a study design COPEC.

The SVOC bis (2-ethylhexyl) phthalate is also a new COPEC for soil based on the screening of the data from the 2005 samples; bis (2-ethylhexyl) phthalate is a COPEC in soil for reach TS-1C. The ESL for bis (2-ethylhexyl) phthalate in the ECORISK Database Version 2.2 (LANL 2005, 90032) is lower for terrestrial avian receptors than in the previous version of the database (LANL 2004, 87386) due to a revision to the transfer factor EPA recommended for calculating the dose to avian receptors (LANL 2005, 90032). Bis (2-ethylhexyl) phthalate is a COPEC in sediment only for reach TS-1C. Additional nest boxes were added to reach TS-1C in 2005 as part of the field studies. Therefore the existing studies for the Mortandad watershed include the potential effects of this and other COPECs on avian receptors.

Existing study design COPECs for soil, particularly inorganic COPECs, were designated as study design COPECs for additional reaches as a result of the screening of data from the 2005 samples: cadmium and lead in E-1FW, chromium and copper in TS-2E, manganese in TS-1E, vanadium in TS-1W, and Aroclor-1254 in E-1E. Mercury is now a study design COPEC in a number of additional reaches because of an updated transfer factor EPA recommended for calculating the ESL for avian species (LANL 2005, 90032), and the current ESL is one-fourth of the ESL used for the original screening in the biota investigation work plan. The additional reaches for which mercury is a COPEC are M-1E, M-2W, M-2E, and M-3. Some existing study design COPECs were also detected at higher concentrations in reaches in which they were already study design COPECs. These COPECs were already considered in the study designs for other reaches and were not detected at concentrations greatly exceeding the concentrations detected in earlier samples. Therefore, no additional studies are indicated for these COPECs based on the screening of the new data.

Additional COPECs for Sediment

Tables E-1.2-4 to E-1.2-6 in Appendix E show the HQs for sediment COPECs based on the screening of the 2005 samples. The maximum detected concentrations of COPCs in sediment for these samples are available in the data files in Appendix C.

Based on the screening of 2005 samples iron is a study design COPEC in active channel sediments. No iron ESL for sediment was available at the time of the screening against ESLs in the biota investigation work plan; the new ESL is based on exposure to aquatic community organisms (LANL 2005, 90032). Based on the screening of the 2005 sediment data, iron would be a study design COPEC in reaches E-1W, M-1E, and M-4. The HQs for all three reaches are similar, and reach E-1W was already included in the study for ecological risk to the aquatic community (the *Chironomus tentans* laboratory toxicity assay). Therefore the existing field studies for the Mortandad watershed address this additional COPEC.

The SVOC bis (2-ethylhexyl) phthalate is also a new COPEC based on the screening of the 2005 sediment data, combined with revisions to ESLs. The ESL for bis(2-ethylhexyl) phthalate in the ECORISK Database Version 2.2 (LANL 2005, 90032) is lower for the avian receptor (the violet green swallow)

exposed to sediment than the ESL in the previous version of the database due to a revision in the transfer factor EPA recommended for calculating the dose to avian receptors. Bis(2-ethylhexyl)phthalate is a COPEC in sediment only for reach TS-1C. Additional nest boxes were added to reach TS-1C in 2005 as part of the field studies. Therefore, the existing studies for the Mortandad watershed include the potential effects of this and other COPECs on avian receptors.

Several existing study design COPECs for sediment are designated as study design COPECs for additional reaches based on the screening of the 2005 sediment data. Anthracene is now a study design COPEC for aquatic community organisms in sediment in two additional reaches, E-1E and M-2W. Mercury is now a study design COPEC for avian receptors in reach M-1E in addition to the existing reaches for which it was already a study design COPEC. These COPECs were considered in the study designs for aquatic community and avian species in other reaches and were not detected at concentrations greatly exceeding the concentrations in earlier samples. Therefore, no additional studies are indicated for these COPECs based on the screening of data from the 2005 sediment samples.

Additional COPECs in Surface Water

Samples of nonfiltered nonstormwater (nonstormwater includes base flow, snowmelt, and persistent pools), filtered nonstormwater, and filtered stormwater were collected from individual water locations within the Mortandad watershed in 2005. Tables E-1.2-7 to E-1.2-12 in Appendix E show the HQs for surface water COPECs based on the screening of the 2005 samples. The maximum detected concentrations of analytes in surface water for these samples are available in the data files in Appendix C.

In the filtered nonstormwater samples (see Tables E-1.2-7 and E-1.2-8 [Appendix E]), two additional surface water COPECs were designated. Cobalt had an HQ of 4.7 for the maximum detected concentration in reach E-1FW. E-1FW was not included in the aquatic studies, but these surface water screening results are unlikely to indicate a widespread ecological risk within the watershed as the HQ in only one reach exceeded 3. Iron, which did not have an ESL for water at the time of the screening presented in the biota investigation work plan, is designated as a study design COPEC for reaches E-1FW, E-1W, and M-1W. Reaches E-1W and M-1W were already included in studies both for toxicity to aquatic invertebrates and toxicity to algae. (Radium-226 was already a study design COPEC for water based on the screening conducted by subwatershed for the biota investigation work plan.) The screening of the 2005 samples confirmed that radium-226 should be considered as a study design COPEC for reaches E-1E, M-1W, M-1E, and M-2W.

In the nonfiltered nonstormwater (see Tables E-1.2-9, E-1.2-10, and E-1.2-11 [Appendix E]), cobalt is also designated as a new study design COPEC in reaches E-1FW and TS-1W. Iron was designated as a new study design COPEC in reaches E-1FW, E-1W, M-1W, M-1E, TS-1C, and TS-1W. Radium-226 was already a study design COPEC for water based on the screening conducted for the biota investigation work plan. The screening of the 2005 samples confirmed that radium-226 should be considered as a study design COPEC for reaches E-1W, M-1W, and M-2W.

No new COPECs were detected in the filtered stormwater samples from 2005; the HQs for filtered stormwater are shown in Table E-1.2-12.

8.1.1.2 Literature Search in Known Ecological Effects

The following is a synopsis of the screening ecological receptors with the highest HQs (HQ >3) and the feeding guilds they represent. This section reviews both the original COPECs from the biota investigation

work plan and the new COPECs designated based on the screening of the 2005 data. The toxic effects are based on toxicity studies used as the basis for the ESLs as described in the ECORISK Database Version 2.2 (LANL 2005, 90032) and are summarized in Appendix E in Tables E-1.1-2 through E-1.1-7. The section below also reports the count of sediment investigation reaches in which the study design COPECs are located. The names of these reaches and HQs for screening against individual receptors can be found in Tables D-2.2.1 through 2.2.10 of the biota investigation work plan (LANL 2005, 89328, pp. D-31– D-41).

Mammals

Soil Pathway Receptors

The deer mouse as a representative for mammalian omnivores had HQs greater than 3 for four COPECs: arsenic, manganese, thallium and naphthalene. Study design COPECs were found in 6 of the 23 reaches.

The montane shrew as a representative for mammalian invertevores had HQs greater than 3 for seven COPECs: arsenic, cadmium, manganese, thallium, vanadium, chrysene and naphthalene. Study design COPECs were found in 10 of the 23 reaches.

The red fox as a representative for mammalian carnivores had HQs greater than 3 for three COPECs: cesium-137, Aroclor-1254, and Aroclor-1260. Study design COPECs were found in 4 of the 23 reaches.

Sediment Pathway Receptors

The occult little brown myotis bat as a representative for mammalian aerial insectivores had HQs greater than 3 for three COPECs: aluminum, arsenic, and naphthalene. Study design COPECs were found in 4 of the 23 reaches.

Birds

Soil Pathway Receptors

The American robin (with invertevore diet) as a representative for avian invertevores had HQs greater than 3 for 10 COPECs: copper, lead, mercury (inorganic), silver, vanadium, zinc, Aroclor-1254, bis-2-ethylhexylphthalate, di-n-butyl phthalate, and cyanide (total). Study design COPECs were found in 13 of the 23 reaches.

The American kestrel (with flesh diet) as a representative for avian carnivores had HQs greater than 3 for three COPECs: mercury (inorganic), cesium-137, and Aroclor-1254. Study design COPECs were found in 1 of the 23 reaches.

Sediment Pathway Receptors

The violet green swallow as a representative for avian aerial insectivores had HQs greater than 3 for nine COPECs, including aluminum, barium, cadmium, copper, mercury (inorganic), silver, vanadium, zinc, and cyanide (total). Study design COPECs were found in 14 of the 23 reaches.

Terrestrial Plants

The terrestrial plant as a representative of primary producers had HQs greater than 3 for 12 COPECs, including barium, chromium (total), hexavalent chromium, copper, manganese, selenium, silver, thallium, vanadium, zinc, acenaphthene, and endrin aldehyde. Study design COPECs were found in all of the 23 reaches.

Terrestrial Invertebrates

The earthworm as a representative of invertebrate detritivores had HQs greater than 3 for six COPECs: chromium (total), hexavalent chromium, copper, mercury (inorganic), americium-241, and plutonium-239,240. Study design COPECs were found in 15 of the 23 reaches.

Aquatic Community Organisms

Water Pathway Receptors

The aquatic community organism that represents various aquatic functional and feeding guilds had HQs greater than 3 for 13 COPECs: aluminum, barium, cadmium, cobalt, copper, total cyanide, iron, lead, manganese, silver, zinc, americium-241, and radium-226. Most COPECs were identified in samples from station E200, which include COPECs from filtered stormwater.

Sediment Pathway Receptors

The aquatic community organism that represents various aquatic functional and feeding guilds had HQs greater than 3 for 15 COPECs, including barium, copper, iron, mercury (inorganic), silver, acenaphthene, anthracene, dibenz(a,h)anthracene, fluorene, methylnaphthalene, naphthalene, Aroclor-1260, chlordane (alpha), chlordane (gamma), and DDT [4,4'-]. Study design COPECs were found in 9 of the 23 reaches.

8.1.1.3 Conceptual Exposure Model

An ecological scoping checklist was completed for the Mortandad watershed during June and July 2003. A separate Part B checklist was completed for each of several subsets of reaches that were similar in habitat. All the completed ecological scoping checklists appear in Appendix C of the "Mortandad Canyon Biota Investigation Work Plan" (LANL 2005, 89308). In Mortandad Canyon above the confluence with Ten Site Canyon (which includes reaches M-1W, M-1C, M-1E, M-2W, M-2E, M-3W, and M-3E), the terrestrial vegetation cover consists primarily of ponderosa pine, mixed-conifer species, box elder, scrub oak, and various deciduous shrubs. Wetland vegetation (e.g., cattails, rushes, and willows) and aquatic receptors are also found in riparian areas along this part of Mortandad Canyon, particularly in reach M-1W, which contains a cattail wetland. Wildlife noted in this part of the canyon included many species of birds (including bluebirds), burrowing animals, garter snakes, lizards, harvester ants, and evidence of large mammals (deer and bear). Chironomids and stonefly larvae were noted in aquatic areas within reach M-1W. A wide selection of wildlife receptors was noted throughout the reaches within Mortandad Canyon. In Mortandad Canyon east of the Ten Site Canyon confluence (which includes reaches M-4, M-5W, M-5E, and M-6), the vegetation cover consists of piñon-juniper woodland, with scattered ponderosa pine, and numerous shrub species and many of the same wildlife species seen in the Mortandad Canyon reaches farther west. In Effluent Canyon (which includes reaches E-1FW, E-1W, and E-1E), terrestrial plant species include ponderosa pine and wetland species (willows, rushes, and cattails) that were common throughout reach E-1W. In Ten Site Canyon (including reaches TS-1W, TS-1C, TS-1E, TS-2W, TS-2C, TS-2E, and TS-3), the vegetation cover includes ponderosa pine, mixed-conifer

species, and oak, along with deciduous shrubs and forbs and associated terrestrial wildlife species. Some areas of riparian and aquatic vegetation (willows, rushes, and cattails) occur in reaches TS-1C, TS-2W, TS-2C and TS-2E. Reach TS-2E also contained aquatic insects at the time of the site visits. The unnamed tributary canyon that heads in TA-05 (including reaches MCW-1 and MCW-2) contains ponderosa pine mixed with piñon-juniper woodland and some shrub oak with a low level of vegetative cover.

Some of the reaches also represent potential or actual habitat for T&E species (Keller 2004, 87688). All the reaches considered in this study are rated as low potential forage areas for the bald eagle except for reach M-6, which is rated as a moderate potential forage area for the eagle. The Mexican spotted owl, however, is believed to actively use several reaches within the canyon (E-1E, M-2W, M-2E, and M-3W). Additional reaches (TS-1E, all TS-2 reaches, and M-3E) are designated as very high potential foraging area, with a number of other reaches considered high or moderate as potential foraging area for the Mexican spotted owl (Keller 2004, 87688). Reaches M-1W and E-1W both contain habitat in which the southwestern willow flycatcher may be assumed to forage at a moderate frequency (Keller 2004, 87688), although this species has not yet been observed in the watershed. The biota studies therefore include explicit consideration of risk to both the Mexican spotted owl, which nests within Mortandad Canyon, and the southwestern willow flycatcher, for which potential habitat exists within the Mortandad watershed.

Surface water in the Mortandad watershed originates either as effluent releases, stormwater, or snowmelt runoff. Where present, surface water can be discontinuous within a reach, alternately stopping where the flow entirely infiltrates into alluvium and emerging downstream where the alluvium thins. Transitions from alluvial channels to bedrock channels are common locations of surface water as water discharges from the shallow alluvial groundwater. Table D-2.3-1 in the “Mortandad Canyon Biota Investigation Work Plan” (LANL 2005, 89308) presents the results of a survey of surface water occurrence in the Mortandad watershed.

Historical contaminant releases to the soils, sediments, and persistent surface water in the Mortandad watershed have occurred from multiple SWMUs and AOCs, primarily through releases of effluent, as discussed in Section 2.1. For ecological receptors, the primary impacted media in the canyons are sediment deposits in the canyon bottoms, surface water derived from effluent releases or persistent pools, and reaches of water that remain for some time after periods of runoff. Active channel sediments (c1 geomorphic unit), potentially subject to persistent water, are referred to as “sediment” in this section. Sediment in other geomorphic units (abandoned channels and floodplains) is referred to as “soil” in this section. The active channel sediments in the Mortandad watershed were also evaluated as part of the soil because all sediments within any of the reaches may be exposed and dry for at least some period of the year, and therefore terrestrial receptors could also be exposed to these sediments.

Persistent surface water exists only in limited sections of the active channel in the watershed. Even so, all active channel deposits are considered in this assessment to be potentially subject to persistent flow under different climatic conditions and therefore to potentially harbor aquatic receptors, i.e., organisms dependent on water, such as algae or chironomids (LANL 2004, 87630, p.26). Floodplains and abandoned channels generally have well-developed terrestrial plant and animal populations and do not support truly aquatic species. Thus, only active channel sediments and surface water potentially have complete exposure pathways to truly aquatic species, whereas terrestrial animals and plants are exposed to COPECs in surface water, soil, or sediment. It is important to recognize that the aquatic species in the watershed represent a fairly simple food web that does not include aquatic vertebrates because surface water is limited both spatially and temporally.

Exposure pathways to terrestrial receptors can occur through the following:

- Air—through respiration of vapors, inhalation, and deposition of particulates
- Surface soil—through root uptake and rain splash on plants, food web transport to plants and animals, incidental ingestion of soil, dermal contact with contaminated soil, and external irradiation
- Persistent surface water and sediments—through root uptake and rain splash on plants, food web transport to animals, incidental ingestion of water and sediment, dermal contact with contaminated water or sediment, and external irradiation from sediment

The major soil-related exposure pathways are plant uptake, food web transport, incidental ingestion of contaminated soil, and external gamma radiation exposure. Water and sediment pathways are of lesser importance to terrestrial receptors because of the limited temporal and/or spatial extent of persistent surface water in the watershed. Exposure to vapors is unlikely because of the infrequent detection of VOCs in the watershed, the low VOC concentrations measured in sediment and water, and the rapid volatilization of VOCs in sediments near the ground surface. Exposure to airborne particulates is a minor pathway because of the limited amount of contamination at the ground surface and the dense plant cover in some reaches.

The remaining pathways related to exposure to surface soil (dermal contact) and surface water and sediment (food web transport, incidental ingestion of contaminated sediment and water, dermal contact, and external radiation exposure) are also minor because of the limited amount of contamination at the ground surface or in surface water. In addition, soil exposure pathway analysis EPA performed to support the development of its ecological soil screening levels (Eco-SSLs) has shown that inhalation and dermal pathways contribute a small fraction of the dose obtained orally (EPA 2003, 76077). All complete exposure pathways are at least qualitatively evaluated in the assessment in this report because some of the measures proposed in this investigation are field measures of effect or exposure.

8.1.1.4 Assessment Endpoints

Assessment endpoints consist of an entity (a receptor species) and an attribute (survival, growth, or reproduction) of that entity that is being assessed. Seven assessment endpoints for the Mortandad watershed are identified based on the study design COPECs summarized in Section 8.1.1.1 (and the associated tables) and the conceptual exposure model. These endpoints were selected to represent T&E receptors (the Mexican spotted owl and the southwestern willow flycatcher) as well as receptors that are representative of the terrestrial and aquatic food web in the Mortandad watershed (food webs are shown in Figures 3.4-1 and 3.4-2 of LANL 2004, 87630). The conceptual exposure model indicates that ingestion exposure pathways and, in particular, food web transport, are important pathways for these COPECs. Assessment endpoints were developed for the five terrestrial feeding guilds (including aerial insectivores) that represented the receptors with the highest HQs, as well as for the surrogates for the T&E species. Because aquatic environments in the Mortandad watershed are generally not perennial and rely on effluent and persistent water from storm runoff, a single assessment endpoint for the aquatic study design was selected. The seven assessment endpoints (AE1 through AE7) are as follows:

- Survival and reproduction of the Mexican spotted owl (AE1)
- Population abundance or persistence and species diversity of avian ground invertevore feeding guild species (e.g., American robin, bluebird) (AE2)

- Population abundance or persistence and diversity of mammalian invertevore and omnivore feeding guild species (e.g., shrews and deer mice) (AE3)
- Survival and growth of detritivore species (earthworms) (AE4)
- Native plant species presence and diversity (AE5)
- Survival and reproduction of the southwestern willow flycatcher (AE6)
- Abundance and survival of the aquatic community in the reaches of the Mortandad watershed that retain surface water long enough to support aquatic communities (AE7)

Assessment endpoints were used as the basis for developing the measures of exposure and the measures of effects. Those measures evaluate impacts to the attributes of survival, growth, or reproduction in the receptor species and in the feeding guilds that those receptor species represent. The measures included field, laboratory, and model data. For the biota investigation in the Mortandad watershed, the measures are based on extension of the field biota investigation done in the Los Alamos and Pueblo watershed (LANL 2004, 87390).

8.1.2 Study Design, Field Verification, and Site Investigation

This section discusses the ecological risk assessment study design, field verification, and site investigation; this encompasses ERAGS steps 4 and 5 and the first part of step 6. Biological data were collected as measures of exposure and effect (lines of evidence) to evaluate the potential for adverse ecological effects from contaminants in soil, sediment, and persistent surface water. The initial design of each study is documented in the "Mortandad Canyon Biota Investigation Work Plan" (LANL 2005, 89308). As a result of discussions with NMED during the review of the biota investigation work plan, an additional measure was added. Algal toxicity tests were added to assess potential risk to algae from radionuclides in surface water. These algal toxicity tests are described in Section 8.1.2.11. Figure 8.1-1 shows reaches and the sample locations in the Mortandad watershed and the background site (reach LA-BKG). Shrews were trapped in two of the reaches (E-1W and LA-BKG) designated for the general small mammal trapping. The plant diversity field studies were conducted in the same reaches indicated for the plant and earthworm toxicity studies. Field bird surveys are not indicated on the map because they did not correspond directly to individual locations in reaches, as explained in Section 8.1.2.5. The rapid bioassessment characterization studies were collocated with the chironomid toxicity tests indicated in Figure 8.1-1. Table 8.1-1 shows the reaches included in each type of study, as well as the study design COPECs used as the basis for including that reach for that type of study.

8.1.2.1 Small Mammal Trapping and Analysis of Pelts and Carcasses

Trapping small mammals was conducted in three reaches within the Mortandad watershed and one background reach in Los Alamos Canyon. The results of the trapping determined measures of effect on the small mammal population including relative abundance, species composition, reproductive status, and body weight. The field measures of the small mammals were lines of evidence for the effects to the small mammals themselves (see Table D-4.0-4 in LANL 2005, 89308) in support of AE3.

Small mammals were also collected for laboratory analysis to determine the concentration of COPECs in tissues. The concentrations in the tissues were lines of evidence for the exposure of the Mexican spotted owl (AE1) as well as for the mammalian carnivore (the red fox), which was not designated as an individual assessment endpoint. All the individuals of most species from each reach were separated into pelts and carcasses; the pelts and carcasses were then combined so that one pelt and one carcass sample from each species was sent for analytical analysis for each reach. The exception is for shrews, which were too

small to allow separation into pelt and carcass, and instead whole body samples were submitted. Table B-3.0-2 shows the sample IDs associated with these tissue samples as well as the weights for the composite pelt and tissue samples from each species. Individuals of some species (particularly wood rats) have enough mass that not all animals trapped were included in the composite pelt and carcass samples. Also, animals that tested positive for Hanta virus after collection were not included in the composite samples.The total number of animals trapped of each species is discussed in Section 8.1.3.4. The number of animals collected (excluding released or hanta virus infected animals) for each pelt or carcass sample from each reach is shown in Table 8.1-2.

The analytical suites were prioritized based on study design COPECs for predators, as shown in Table D-6.0-2 (LANL 2005, 89308). Analyses conducted on these carcass and pelt samples included EPA Method SW-846 6010B metals, perchlorate, mercury, PCBs, americium-241, cesium-137, and strontium-90.

As discussed in Section 7.1.2, cyanide is designated as a study design COPEC based on sediment concentrations exceeding the BV only in reach MCW-2W. Resampling done in that location and two adjacent locations in the same area produced values below the BV (see Section 7.1.2 and Tables E-1.2-1 and Table E-1.2-4). Cyanide was therefore not considered further in sediment in this investigation report. Total cyanide was also designated as a study design COPEC for aquatic organisms in the biota work plan based on detected concentrations in water at gage station E200 (Table B-7.1-1 in LANL 2005, 89308). Water from E200 was collected as the reach M-2W sample and included in the algae toxicity studies. Neither this water sample nor any other new water samples from other reaches contained cyanide at concentrations that would make cyanide a study design COPEC (see Table E-1.2-7 and E-1.2-9) at this water station or the others sampled. Cyanide was detected in water for the algae test only in the samples from TS-1C and TS-2C, and the concentrations were less than 3 μg/L. Sediment from reach M-2W was also used for the chironomid toxicity test to assess risk to aquatic organisms. Regression analysis was conducted for each analyte detected (except sodium) in the carcass or pelt samples of each species, even if the analyte was not a study design COPEC. These regression analyses compared the concentration of a COPEC in the composite sediment samples collected at the trapping arrays, discussed in Section 8.1.2.2, against the concentration of the COPEC detected in tissues. Some analytes were detected in some tissue samples but not other samples; plots and regressions for analytes that were detected at least once in tissue include nondetects for that analyte as values at their detection limit

8.1.2.2 Soil Characterization

Samples of sediment were collected from the locations in the Mortandad watershed used for laboratory toxicity tests and also from sediment within the small mammal trapping arrays for additional characterization of exposure to small mammals. Table B-3.0-3 shows the reach, location ID, and geomorphic unit associated with each of these samples. For the earthworm and plant toxicity tests, discrete samples were collected from 0–30 cm (0–1 ft) for the toxicity assays and for the analytical analysis of the same samples. Samples for the earthworm and plant toxicity tests were collected from geomorphic units outside the active channel (generally c2, c3, or f1 units). Sediment samples for the *Chironomus tentans* toxicity tests were collected from 0–15 cm (0-0.5 ft) in the c1 geomorphic unit (the active channel) to represent the sediment to which these aquatic organisms would be exposed. At the four sites for the small mammal trapping, composite samples were collected for Laboratory analysis to estimate COPEC concentrations the mammals would be exposed to. The composite samples consisted of 10 subsamples collected from 0–15 cm (0–0.5 ft) at 10 locations within each trap array.

8.1.2.3 Owl Pellet Analysis

Owls regurgitate pellets containing fur and bones from prey items they have consumed; the contents of these pellets were examined to determine the species of prey consumed as an ancillary line of evidence for AE1. For this study, 46 pellets collected from four owl roosting sites were sent for taxonomic identification of the bone and tooth fragments (Bennett et al. 2006, 93774). Three of the roosting sites are known to be occupied by the Mexican spotted owl. One roosting site lies within Mortandad Canyon near reach M-2W. Two additional Mexican spotted owl roosting sites are in Cañon de Valle. The analysis of species included 17 taxonomic groups of mammals as well as birds. The complete list of number and type of each species found is described in Bennett et al. (2006, 93774). The primary use of this information in this study was to determine which species of small mammals from the tissue COPEC concentration analysis were appropriate to use for modeling the COPEC concentrations ingested during prey consumption by the Mexican spotted owl, as described in Section 8.1.2.1. The results of this comparison are described in Section 8.1.3.1.

8.1.2.4 Nest Box Studies

An avian nest box monitoring network has existed in the vicinity of the Laboratory since 1997; the network includes both potentially contaminated and noncontaminated areas. As part of the baseline ecological risk assessment for the Mortandad watershed, additional nest boxes were placed in the canyon bottoms or canyon bench areas within Mortandad Canyon and its major tributary canyons. Figure 8.1-1 shows the boxes within the Mortandad watershed that were sampled for the biota studies. Both the western bluebird (*Sialia mexicana*) and the ash-throated flycatcher (*Myiarchus cinerascens*) occupy these boxes. Measures collected using the nest box network included field measures of effect on reproductive success of these avian species (including clutch size, fledgling success, growth of fledglings, etc.) and measures of exposure through analysis of COPEC concentrations in unhatched western bluebird eggs and unconsumed prey (insects) collected within the boxes. Table B-3.0-5 shows the egg and insect samples collected for analytical analysis within the Mortandad watershed; the locations of the boxes within the reaches are shown in Figure 8.1-1. Boxes in Cañada del Buey and in the Cañada del Buey watershed (near TA-51) and boxes from two areas outside the Laboratory (the Los Alamos golf course and the Guaje Pines Cemetery; LANL 2004, 87390, Figure 8.1-1) were also included in the study for reference. Eggs from individual boxes within a reach were submitted as samples. In some cases, individual boxes contained sufficient material for analysis, but in other cases insects from more than one box in a reach were combined to obtain sufficient sample size for analysis. Table 8.1-3 shows a summary of the eggs and insects collected per reach.

Because of sample size limitations, egg and insect samples were analyzed only for metals. These measures were collected to evaluate AE2, the endpoint for avian ground invertevores. The COPEC concentrations in nest box insects were used as a measure for AE6, the avian insectivore (southwestern willow flycatcher) and the mammalian insectivore (the occult little brown myotis bat); the bat is being evaluated for possible exposure through prey even though this species does not represent a specific assessment endpoint in the baseline ecological risk assessment studies. Results of the field measures of effect through reproductive success are discussed in Section 8.1.3.3. The measures of exposure through COPEC concentrations measured in insects are discussed in Section 8.1.3.2 and exposure based on COPEC concentrations in eggs is discussed in Section 8.1.3.3.

8.1.2.5 Breeding Bird Survey

An additional study done as a measure for AE2 and AE6 for the avian ground invertevore and the avian insectivore was a survey of the level of use of upper Mortandad Canyon and Ten Site Canyon by avian

species. The survey recorded species, sex, and age of birds within these canyon bottom areas and provides an estimate of the diversity of species in the survey areas. The survey areas were not restricted to the designated reach areas but included birds seen or heard in the majority of the canyon bottoms in these areas during the walkover survey. The complete survey results are presented in Keller (2005, 93690). The results relevant to this investigation are discussed in Section 8.1.3.3.

8.1.2.6 Earthworm Toxicity Tests

Sediment collected from the 0- to 30-cm (0- to 1-ft) depth interval was used for the earthworm toxicity tests (a measure for AE4). The earthworm tests used the standard American Society for Testing and Materials (ASTM) method E1676-97. The toxicity tests compared the growth and mortality of the earthworms from the seven reaches shown in Table 8.1-1 with the reference site in reach LA-BKG. As shown in the table, the reaches were selected to represent a gradient of concentrations for COPECs associated with both the soil invertebrate receptor and the mammalian and avian receptors that feed on the soil invertebrate. The biota investigation work plan (LANL 2005, 89308) originally proposed that this assay would also include a bioaccumulation test to determine concentrations of COPECs in the worm tissues after 28 days' exposure to the sediment samples. Unfortunately, the earthworms were inadvertently discarded at the conclusion of the test before being sent for laboratory analysis for COPEC concentration. Therefore, the dose to avian receptors in Section 8.1.3.3 is calculated based on concentrations detected in earthworms in the Los Alamos and Pueblo Canyon studies (LANL 2004, 87390) from sediments with the same COPEC concentrations or on extrapolated values from those studies. Section 8.1.3.5 discusses the results of the statistical analysis of the growth and mortality between sites.

8.1.2.7 Seedling Germination Tests

Sediment collected from the 0-30-cm (0-1-ft) depth interval was used for the plant toxicity tests (a measure for AE5). The plant toxicity tests used the standard ASTM method E1963-98. The plant toxicity tests compared survival rates, shoot height, root length, and shoot and root mass in plants grown in soil the same seven locations used for the earthworm toxicity tests with plants grown in the soil sample from the background site. The tests used yarrow (*Achillea millefolium* L. var *occidentalis*), which has more variable results than some other available test species of plant but is more relevant to the ecosystems found at the Laboratory. Section 8.1.3.6 discusses the results of the statistical analysis of the growth and mortality between sites.

8.1.2.8 Plant Survey

A field plant survey was conducted in reaches within the Mortandad watershed to provide ancillary information for the small mammal trapping (AE3); significant differences in the amount of plant cover may affect the number or type of small mammals caught. The field plant survey also serves as an ancillary line of evidence for ecological risk to plants (AE5), although the plant toxicity test is the major line of evidence for that assessment endpoint. The plant survey encompassed nine reaches (see Table 8.1-1) including all of the mammal trapping reaches, all reaches for the plant and earthworm toxicity tests, and the background reach.

In these surveys, vegetation was identified as tree, shrub, forb, cacti, or graminoid (with identification to species where possible) and percent canopy cover for each species was categorized (Balice and Sandoval 2006, 93689). Two measures of diversity, the Shannon diversity function and species richness, were used to compare the vegetation between sites. A brief summary of the results and their relevance to other measures is provided in Section 8.1.3.6.

8.1.2.9 *Chironomus tentans* Toxicity Test

Sediment samples from the eight reaches shown in Table 8.1-1 were used in the EPA Method 100.2 (EPA 2000, 73776) 10-day growth and survival test with the larval insect *Chironomus tentans*. Each sediment sample was tested at 100% only; dilution series were not run on the sites. Standard control and reference toxicants were included. The endpoints for this test include both survival and growth (as ash-free dry weight). The results of the test are discussed in Section 8.1.3.7.

8.1.2.10 Rapid Bioassessment Characterization

Rapid bioassessment characterization was conducted at five reaches in the Mortandad watershed that had sufficient flow to potentially support aquatic macroinvertebrate communities (Henne and Buckley 2006, 93687), using the EPA Rapid Bioassessment Protocol (EPA 1999, 73728). Collection of aquatic macroinvertebrates was conducted in association with the bioassessment. Collection and assessment were attempted at all reaches specified in Table 8.1-1 in June and September 2005, but becaue of absence of wate,r neither TS-1C nor TS-2C underwent an assessment or invertebrate collection in June 2005. Similarly, reaches M-2W and TS-1C could not be sampled in September due to lack of water. The biota investigation work plan (LANL 2005, 89308) specified use of a Hess sampler to collect aquatic macroinvertebrates when sufficient water was present to use this sampler. However, none of the sites had sufficient water to use the Hess sampler in either June or September 2005. The Hess sampler is needed to collect data for comparison to the NMED Stream Condition Index (SCI); therefore, no comparisons to the SCI were done for the aquatic macroinvertebrate sampling in the Mortandad watershed. Semiquantitative sampling using a D-frame dip net to determine taxonomic composition of macroinvertebrates was done at the sites. The biota investigation work plan indicated that the collected macroinvertebrates would be submitted for Laboratory analysis if sufficient mass could be collected for analysis. The field team was unable to collect sufficient mass of aquatic macroinvertebrates to submit for analysis.

8.1.2.11 Algal Toxicity Test

Water samples collected from the reaches shown in Table 8.1-1 were used for the EPA Method 1003.0 short (96-hr) chronic toxicity algal growth test. This test uses the green algae *Selenastrum capricornutum*. The test methods, conditions, and results are described in Pacific Ecorisk (2005, 91270). Samples were collected from M-2W, E-1W, E-1E, M-1W, and LA-BKG in July 2005 for the test. Locations in TS-1C, TS-1E, and TS-2C were dry at that time, but water samples were collected from these locations in August 2005 for the toxicity test. Controls and reference toxicants were run with both sets of samples. The results of the test are discussed in Section 8.1.3.7.

8.1.2.12 Spatial Modeling Using ECORSK.9.

The ECORSK.9 model was used to model HQs and hazard indices (HIs) across the Mortandad watershed for the Mexican spotted owl, southwestern willow flycatcher, deer mouse, and western bluebird, as presented in Gonzales et al. (2006, 93786). ECORSK.9 includes both canyon and noncanyon sources as well as measured and interpolated concentrations of COPECs from these sources. The model estimates exposure based on an environmental exposure unit (EEU) that consists of foraging throughout the home range centered on known or potential nest sites input into the model. For the Mexican spotted owl, the model restricted the nest sites to within the buffer area for this T&E species. For the southwestern willow flycatcher, the model restricted the nest sites to within the wetland area designated as potential flycatcher habitat. For the deer mouse and western bluebird, the modeled area included the entire Mortandad watershed west of SR 4. The model produces mean total HIs that provide

an estimate of risk to populations and are most useful for species such as the deer mouse and western bluebird. For evaluating T&E species, risk to individuals and therefore the number of individual grid cells with elevated HIs are a better indicator of locations and COPECs that may need additional investigation. The model calculates both unadjusted HQs and HIs and adjusted HQs and HIs; the adjusted values do not include the contribution of background concentrations of COPECs. For this investigation report, the model was run with two scenarios: In the first scenario all nondetects were included as values at one-half of their detection limit. For many organic chemicals, nondetects constituted 75% to 98% of the data set values, resulting in detection limits heavily influencing the HQ and HI values. To overcome this problem, a second scenario was run in the model in which nondetects for organic chemicals were treated as zeros to focus the results on the actual detected COPECs in the model.

8.1.3 Characterization of Exposure and Effects

This section discusses the baseline ecological risk assessment characterization of exposure and effects, which represents the second part of ERAGS Step 6. This section provides the results from the studies and their interpretation as well as the supporting information in tables and figures. Revised calculations of dose to predators based on concentrations of COPECs in prey are also presented in this section. Although the screening of concentrations of COPCs in sediment and water samples collected in 2005 is also a line of evidence supporting the evaluation of potential ecological risk in the Mortandad watershed, that evaluation is separate from the field studies conducted for the base line ecological risk assessment. Screening the 2005 sediment and water samples against ESLs is presented in Appendix E and summarized in Section 8.1.1.1.

8.1.3.1 Mexican Spotted Owl

ECORSK.9 Model

In the ECORSK.9 model, a number of grid cells within the Mortandad watershed with elevated HIs indicated there may be areas of potential risk to individual Mexican spotted owls (Gonzales et al. 2006, 93786). This was true for both the unadjusted and adjusted mean HI. The adjusted mean HQ and mean HI values calculated in the second scenario (all organic nondetects treated as zeros, as explained in Section 8.1.2.12) are considered the most representative of potential risk from Laboratory sources to the modeled receptors, although the adjustment for background made little difference for the HQ and HI values for the owl. The adjusted total mean HI with nondetects treated as zeros for the owl is 1.6; only bis(2-ethylhexyl)phthalate had an HQ >1.0. Lead was the second most important COPEC (HQ = 0.6). The HI was ≥1 in 49% of the focal points; almost all of these HIs were less than 10. The area with the highest adjusted HI values indicating potential risk to the Mexican spotted owl were in part of Ten Site Canyon, including TA-35 and reaches TS-2E and TS-2C, and in Mortandad Canyon reach M-2E. Although it is difficult to pinpoint the individual source of elevated HIs in the model for a receptor with a home range as large as the owl, the primary sources of high HI values in the model appear to be from samples from noncanyon sources, particularly sources of COPECs associated with TA-35.The adjusted HI for the grid cell in Mortandad Canyon in which a pair of owls has nested was only 0.2. Therefore, the adjusted HI for the grid cell in Mortandad Canyon containing a confirmed owl nest indicates little to no threat of potential adverse effects from Laboratory-related contaminants.

Concentrations of COPECs in Prey

Remains of prey found in the owl pellets from the collection site near reach M-2W in Mortandad Canyon were dominated by wood rats (*Neotoma sp.*), which made up approximately half the identified pellets (Bennett et al. 2006, 93774). Wood rats were collected and analyzed from all trapping sites except the

LA-BKG site. Deer mice, brush mice, and pinyon mice were also found in pellets from this site. All these species were collected during the small mammal trapping done for this study. Two other pellet collection sites lie outside of the Mortandad watershed but within the home range of Mexican spotted owls at the Laboratory. These two other sites are also used for roosting by the Mexican spotted owl. Pellets from both these sites also contained wood rats; in addition, one site contained the remains of brush mice and another site contained pellets with the remains of long-tailed voles. The analysis of the pellets collected from these three sites indicate that the species collected from the small mammal trapping locations are appropriate to use in the refined calculation of the estimated doses to the Mexican spotted owl. The dose was calculated using the maximum detected concentrations in any prey species, although because wood rats may represent the dominant prey species; use of maximum concentrations from other species may overestimate the dose to the Mexican spotted owl.

COPECs for the Mexican spotted owl were identified in the initial screening of the sediment data (LANL 2005, 89308, p. D-37). While only Aroclor-1254 met the criterion for a study design COPEC (HQ >1 for a T&E species), mercury and cesium-137 had HQs just above 0.8. These three COPECs were not detected in the tissues of the small mammals sent for Laboratory analysis in this study. The detection limits for mercury and Aroclor-1254 are conservatively used to represent the tissue concentration in the refined dose calculation for the Mexican spotted owl. Cesium-137 results are not used in the dose calculations, as discussed below. Based on comments by NMED (NMED 2005, 92084), selenium is also a study design COPEC for all avian receptors although the HQ did not indicate that selenium should be included.

Small mammals are also assumed to be the prey of the receptor representing the carnivorous mammal, the red fox. Study design COPECs for the fox identified in the screening conducted for the biota investigation work plan (LANL 2005, 89308, p. D-35) include cesium-137, Aroclor-1254, and Aroclor-1260. Detected concentrations of Aroclor-1260 are used in the refined estimate of the dose to the fox, and the detection limit for Aroclor-1254 is conservatively used as tissue concentrations for this COPEC.

As described in the biota investigation work plan (LANL 2005, 89308 p. D-14), an HQ for the owl can be calculated by dividing the avian toxicity reference value (TRV) for a COPEC from the ECORISK Database, Version 2.2 (LANL 2005, 90032) by the normalized food intake of the owl of 0.102 mg fresh weight (fw) food/kg body weight (bw)/day (LANL 2005, 89308, p. D-14). Because the TRV for cesium-137 is based on a radiation dose to the organism and not on an amount ingested, this COPEC is not amenable to these calculations. Table 8.1-4 shows the calculations to combine the maximum detected concentrations in carcass and pelt into the equivalent concentration in a whole animal. This table also shows the HQ calculated by dividing the concentration in the reconstructed whole animal by the food ESL calculated as described above. The proportions of methylated mercury and inorganic mercury in the tissues were not measured, but the calculations in Table 8.1-4 demonstrate that the HQ is <0.5 for the owl regardless of whether the mercury is in the inorganic or methylated form.

8.1.3.2 Southwestern willow flycatcher

ECORSK.9 Model

In the ECORSK.9 model, a number of grid cells within the Mortandad watershed with elevated HIs indicated there may be areas of potential risk to southwestern willow flycatchers (Gonzales et al. 2006, 93786). This was true for both the unadjusted and adjusted HI. The adjusted mean HI value for the flycatcher was 6.2. The dominant COPECs were mercury (HQ = 1.7), di-n-butyl phthalate (HQ = 1.5), boron (1.4), and bis (2 ethylhexyl) phthalate (HQ = 0.48). HIs were ≥1.0 in 81% of the grids; approximately half of these HIs were less than 10. The flycatcher was modeled only for areas that contain

flycatcher habitat; therefore, the area with elevated HIs are limited to the Effluent Canyon area. The elevated HQs for di-n-butyl phthalate resulted primarily from measured values in the noncanyons portion of the data set used in the ECORSK.9 model. There is no BV for boron, and it is unknown whether the detected boron values represent releases from Laboratory sites or instead background levels.

Concentrations of COPECs in Prey

This section estimates the potential dose to the southwestern willow flycatcher using the concentrations in the insects collected from the nest boxes. As described in the biota investigation work plan (LANL 2005, 89308, p. D-14), an HQ for the flycatcher can be calculated by dividing the avian TRV for a COPEC from the ECORISK Database Version 2.2 (LANL 2005, 90032) by the normalized food intake. For the flycatcher, normalized food intake was calculated from the body weight of 12.7 g (LANL 2005, 89308, p. D-14) and estimating the food ingestion rate using the allometric equation for passerine birds from EPA's Wildlife Exposure Factors Handbook (EPA 1993, 59384, equation 3-4). The calculated food ingestion rate is 0.0034 kg/day. This food ingestion rate is in grams of dry weight per day, and was converted to fresh weight using the dry weight to fresh weight ratio for honeybees (Fresquez and Ferenbaugh 1999, 91269). The final insect ingestion rate used in the calculations for the southwestern willow flycatcher is therefore 0.79 kg fw food/ kg bw/day. Table 8.1-5 shows the calculated HQs for the flycatcher based on ingestion of the concentration measured in nest box insects. In some reaches, more than one insect sample could be analyzed, so the arithmetic mean of the concentrations was used (nondetects treated as one-half of the detection limit) as the sample size was too small for calculation of a UCL of the mean. In reaches with only one insect sample analyzed, the maximum detected concentration was used.

The HQs for food ingestion are shown in Table 8.1-5 and predict a much lower level of potential ecological risk than the screening against ESLs did, even though HQs for five COPECs still exceed one (barium, copper, mercury [assumed to be methyl], vanadium, and zinc). Four of these COPECs also had HQs elevated above one in samples collected outside the Mortandad watershed in the Cañada del Buey, Pueblo, and Rendija watersheds. The concentration of these metals in insects is therefore unlikely to be correlated with the concentration of COPECs in soil. The TRVs for these metals probably result in an overprediction of riskbecause the TRV is likely to be based on a more toxic form of the COPEC than is found in the insects. In addition, the southwestern willow flycatcher has not been observed in this part of the Laboratory, so the risk is hypothetical at this time. However, further evaluation may be warranted if the flycatcher is observed to utilize this area in the future.

Bis(2-ethylhexyl)phthalate could not be evaluated in this study, as the mass of insect tissue collected was sufficient only to run the metals analytical suite. However, potential effects of bis(2-ethylhexyl)phthalate are considered in the nest box study evaluation described in Section 8.1.3.3.

8.1.3.3 Avian Invertevore Feeding Guild

This section provides results for trends of COPEC concentration in sediment versus field measures for the avian invertevore feeding guild in the Mortandad watershed, such as nest success and eggshell thickness. This section also evaluates trends of COPEC concentration in sediment versus concentration in eggs. Field measures are derived from Colestock and Fair (2005, 93691).

Nest Success for Bluebirds

As part of the Laboratory's nest box monitoring program, a large number of field measures are collected from the nest boxes each year (Colestock and Fair 2005, 93691). Two of these measures that relate to

juvenile survival were selected for this study for comparison to concentrations of COPECs in sediment. The measures selected are percent fledged and percent female (the latter may relate to specifically to PCBs as COPECs). Occupied bird boxes were found in five reaches within the Mortandad watershed: M-3, M-4, M-5, TS-2C, and TS-2W. All species occupying the nest boxes (western bluebirds, violet green swallows, ash-throated flycatchers, and mountain bluebirds) are included in the analysis of the measures to provide a larger dataset as the overall number of occupied boxes in the reaches is fairly small. Appendix E provides box plots comparing these two measures between species; no significant differences are seen. Comparisons of the selected nest measures between these reaches are shown in Figure 8.1-2 for percent fledged and Figure 8.1-3 for percent female. Boxes in these figures indicate the interquartile range of the sample results, with the upper and lower ends defined by the 75th and 25th percentiles, respectively. Horizontal lines within the boxes indicate median values, and horizontal lines above and below the boxes represent the 5th and 95th percentiles of the data. Neither measure appears to differ significantly between the reaches, but there are small sample sizes for some measures (e.g., percentage of females in reaches TS-2C and TS-2W). These measures were recorded from 1997 to 2005; bivariate plots of each measure versus year were made and are shown in Appendix E. These measures do not correlate significantly with the year, so data from all years are included on the plots.

In addition to the comparison conducted between reaches, the combined data from all reaches within the Mortandad watershed are compared with other areas within the nest box monitoring network. The groups are Mortandad (Mort), Cañada del Buey (CdB), the cemetery (Cem, unimpacted area), the golf course (GC, unimpacted area), TA-35 (impacted, boxes are near SWMUs or AOCs), Los Alamos and Pueblo Canyons (LA/P, impacted by SWMUs and AOCs), and other (representing the boxes in the nest box network not included in the other groups). Figure 8.1-4 shows a comparison of the percent fledged between the groups and Figure 8.1-5 shows a comparison of the percent female nestlings between the groups. For both measures the results for the Mortandad watershed do not differ from the other areas.

Eggshell Thickness

Another set of parameters collected as part of the nest box network are related to the condition of the eggs. Numerous parameters have been collected; three of these parameters were chosen for inclusion in this study. Eggshell length (in millimeters) and total egg weight correlate well with each other and provide an estimate of egg size. Eggshell thickness was also chosen because previous studies had shown that some thinning of eggshells has occurred in Sandia Canyon (Fair and Meyers 2002, 82655). As with the other nest measures described above, all species are included to provide a larger dataset. Appendix E shows the comparison between species for egg length, egg weight, and eggshell thickness; the comparison shows no significant differences between species for these parameters. Appendix E also compares length, weight, and thickness across years in bivariate plots. None of the three measures vary significantly with year, so data from all years are included in the analysis.

The measures for the eggs are compared between the same five reaches (M-3, M-4, M-5, TS-2C, and TS-2W) as the other nest measures and are also compared among the same areas (Mortandad, cemetery, golf course, Cañada del Buey, TA-35, Los Alamos and Pueblo Canyons, and other). Figures 8.1-6 to 8.1-8 show the comparisons for the egg measures between reaches within the Mortandad watershed. Figures 8.1-9 to 8.1-11 show the comparisons for these measures between the areas. The sample sizes vary between reaches and between groups; however, the three measures do not show any significant differences between reaches or between groups.

COPEC Concentration in Eggs

The concentrations of metals measured in eggs were plotted against the reach average sediment concentration of that COPEC in the reach from which the egg was collected. The concentration in eggs does not correlate significantly with the concentration in sediment for any of the metals. The plots and regression calculations for all metals are presented in Appendix E. For two of the metals that generated higher HQs for the robin—mercury and copper—in the screening conducted for the biota plan and that were detected in the eggs, the graphs are presented in Figures 8.1-12 and 8.1-13. In addition, NMED requested retaining selenium for all evaluations in the report (NMED 2005, 92084), even though the initial screening did not show this as a COPEC; therefore the graph for selenium is presented in this section in Figure 8.1-14.

COPEC Concentration in Worms

As discussed in Section 8.1.2.6, COPEC concentrations in earthworms were not obtained from the Mortandad watershed in this study. Therefore estimates of potential risk to birds in the avian invertevore feeding guild cannot be directly made using measured concentrations in earthworms. In this report, regressions based on data from the Los Alamos and Pueblo watershed (LANL 2004, 87390) are used to estimate potential concentrations in earthworms in the Mortandad watershed for COPECs that had a significant correlation between detected concentrations in soil and worms in the Los Alamos and Pueblo watershed. For COPECs without significant correlations, the transfer factor from the ECORISK Database Version 2.2 (LANL 2005, 90032) is used. For both types of calculations, the concentration of the COPEC in the composite sample used for the earthworm toxicity test in a reach is used to estimate the concentration in earthworms from that reach. This estimated concentration in the worms is then compared with the concentration in food items expected to have no toxic effects (the food ESL) to derive an HQ for each reach reflecting risk from consumption of earthworms exposed to soil from that reach. Table 8.1-6 shows the basis of the calculations of the estimated concentrations in the worms, the food for each COPEC, the concentration in each soil composite sample by reach, and the HQ from worm ingestion. Two of the two organic COPECs (bis(2-ethylhexyl)phthalate, di-n-butyl phthalate) are not included in Table 8.1-6 because neither COPEC was detected in any of the soil composite samples used in the earthworm toxicity tests. An HQ >3 appears in all reaches, including the reference reach, for mercury based on assuming all mercury is in the methylated form. Only reach E-1E shows an HQ >3 for mercury in the non methylated form. Risk from both types of mercury are included in the table to provide bounding estimates. Because mercury speciation was not measured, the actual ratio of methylated to non methylated mercury in soil and worms is not known. No COPECs, except mercury, produced an HQ >3 in the modeling of dose through earthworms.

Field Surveys of Bird Abundance and Diversity

Field surveys of bird species were done in two areas: Mortandad Canyon from reaches M-1 through M-2, and adjacent parts of Effluent Canyon, and Ten Site Canyon from reaches TS-1 through TS-2, and adjacent areas in Pratt Canyon (Keller 2005, 93690). Species diversity was measured by calculating a Shannon-Weaver Index for each site. The index value was 2.7 for Mortandad and Effluent Canyons and 2.5 for Ten Site Canyon, indicating similar diversity of species between the two areas. The composition of species based on diet type was also similar between the two areas: most of the species in both areas were insectivores (including both ground-feeding insectivores and aerial insectivores). This finding supports using COPEC analysis in earthworms for assessing the risk to avian receptors in the Mortandad watershed.

The surveys yielded similar results for both areas even though there are some differences in bird COPECs between Mortandad and Effluent Canyons and Ten Site Canyon. As shown in Tables D-2.2-6 and D-2.2-8 (LANL 2005, 89308; pp. D-36 and D-38), the study design COPECs for the robin in that part of Mortandad Canyon are predominantly copper, lead, mercury, vanadium, and Aroclor-1254. In Ten Site Canyon, Aroclor-1254 and mercury are also study design COPECs, but other metals have HQs less than 3. Di-n-butyl phthalate was also a study design COPEC only in Ten Site Canyon. Study design COPECs for the violet-green swallow in Mortandad and Effluent Canyons included primarily aluminum and zinc. Other metals (cadmium, copper, mercury, and vanadium) were the dominant COPECs for the swallow in Ten Site Canyon. Both areas have a number of study design COPECs for birds, but the field surveys support that a good diversity of avian species are still found in these areas.

ECORSK.9 Model for Western Bluebird

Based on the ECORSK.9 model (Gonzales et al. 2006,93786), the percentage of the western bluebird population in the Mortandad watershed that has potential for adverse effects predicted by elevated HIs is too low to affect population viability. The adjusted mean HI for the bluebird is 1.2. The dominant COPEC for this receptor based on the adjusted HI is mercury (mean HQ = 0.38). Other metals (cyanide, zinc, and vanadium) dominated the unadjusted HI, but the entire contribution of these three COPECs was attributable to background. HIs in 24% of the focal points were greater than 1.0.

8.1.3.4 Mammalian Invertevore Feeding Guild

Field Surveys of Small Mammal Relative Abundance and Reproductive Status

A variety of field measures were collected during the trapping and collection of small mammals for this biota investigation (Bennett et al. 2006, 93701). The mean percent daily capture rate, which is an estimate of relative population density, was highest in reach E-1W at 22% and lowest in reach LA-BKG at 7%. The results are shown in Figure 8.1-15. The trend within the Mortandad watershed reaches of decreasing mean daily capture rates with distance downcanyon is probably related to habitat; the trend is consistent with the total percent vegetation canopy cover discussed in Section 8.1.3.6. Species diversity expressed as a Shannon-Weaver Index (see Figure 8.1-16) follows the same trend. The HQ and HI values for deer mouse COPECs also decrease downcanyon; so increasing COPEC concentrations cannot be responsible for the drop in capture rates.

Species composition (the frequency of capture for each species at a site) was very similar between the three Mortandad watershed reaches; species composition in all the Mortandad reaches differed from the Los Alamos Canyon reference site. Data collected during the trapping study indicated no differences in ratios of males to females, body weights, or reproductive status between reaches, using chi square analysis (Bennett et al. 2006, 93701); however, the size of the sample set in this study is somewhat small for evaluation of effects on these parameters.

Concentrations of COPECs in Small Mammals

As described in Section 8.1.3.4, several species of small mammals were trapped and collected in each reach used in the study. All the individuals of most species from a reach were separated into pelt and carcass; the pelts and carcasses were combined so that one pelt and one carcass sample from each species was sent for analysis for each reach. The exception is for shrews, where whole bodies were sent for analysis because of the small size of these mammals. Distinct differences in tissue concentration versus sediment concentration were not seen between species. Regression analysis of concentrations of study design COPECs in carcasses of all species and concentrations in sediment are presented in

Appendix E and show statistically significant correlations for only three of the detected COPECs: aluminum, iron, and perchlorate, although two of the correlations are negative. As shown in Figures 8.1-17 and 8.1-18, aluminum and iron concentrations in tissue are negatively correlated with sediment concentrations, indicating no significant uptake by small mammals from the soil. Figure 8.1-19 shows perchlorate in body tissue; perchlorate was positively correlated with sediment concentrations, indicating uptake by small mammals from the soil. At NMED's request (NMED 2005, 92084), selenium was retained as a COPEC in this evaluation. Selenium concentrations in small mammal tissue did not have a significant correlation with concentrations in soil, as shown in Figure 8.1-20. Figures presenting concentrations in carcass and concentrations in soil for all other detected analytes are in Appendix E.

Regression analysis of concentrations in pelts of all species and COPEC concentrations in sediment showed statistically significant correlations for only two of the detected analytes: americium-241 and arsenic. Concentrations of both these COPECs in pelts were positively correlated with sediment concentration. Figure 8.1-21 shows the concentration of americium-241 in pelt versus sediment. Figure 8.1-22 shows the concentration of arsenic in pelt versus sediment. Selenium concentrations in pelt versus sediment are shown in Figure 8.1-23, and indicate a positive correlation**.** In contrast, lead concentrations in pelts seem to be negatively correlated with sediment concentrations, although the regression was not statistically significant ($p = 0.07$ for regression). Because analyses of pelts include soil particles adhering to the pelt, these analyses are not as useful as concentrations in carcasses in indicating potential uptake, although they still provide information for possible transfer to higher levels of the food chain. Appendix E presents regression equations and figures showing concentrations in soil versus concentrations in pelts for other detected analytes. The other study design, COPECs detected in pelt and carcass samples were not correlated with sediment concentrations in the study reaches. Graphs of carcass and pelt concentration versus sediment concentration for all other detected COPECs are presented in Appendix E. For some COPECs, this result may indicate that concentrations in tissues are unrelated to environmental exposure. For COPECs that are known bioaccumulators, such as Aroclor-1260, these results indicate that the sediment in the study reaches is not a significant contributor to the total body burden of these small mammals.

Concentrations in the pelts and carcasses were multiplied by the proportional masses of the pelts and carcasses to reconstruct an estimate of the whole animal body tissue concentration. This information was used in Section 8.1.3.1.1 to refine the estimate of dose to the Mexican spotted owl. The same information is used here for comparison to the results of small mammal trapping studies conducted in other canyons; those studies all used concentrations determined from analysis of whole animals. Regression analysis of estimated concentrations in whole bodies of all species and concentrations in sediment show statistically significant correlations for only two of the detected analytes, with positive correlations for americium-241 and perchlorate. Regression equations and figures showing concentrations in soil versus concentrations in whole animals for other detected analytes are presented in Appendix E.

Concentrations of Aroclor-1260 in small mammals from the Mortandad watershed (except for the shrew, which was not included in previous studies) are similar to concentrations detected in small mammals trapped in the Los Alamos and Pueblo watershed. These two watersheds have similar concentrations of Aroclor-1260 in soil from the mammal trapping areas. This indicates a consistent relationship between this COPEC in soil and in small mammal tissue, indicating that this correlation may have some predictive value.

ECORSK.9 Model for Deer Mouse

The percentage of deer mouse population in the Mortandad watershed that has potential for adverse effects predicted by elevated HIs in the ECORSK.9 model is too low to affect population viability

(Gonzales et al. 2006, 93786). Mean HI values exceeded 1.0 in only 8% of the focal points for the deer mouse. Based on the unadjusted HI (the adjusted HI showed no COPECs with an HQ >0.3), the dominant COPEC would be thallium. Nondetects constituted 72.5% of the thallium values used in the data set, and the mammalian TRV for thallium is very low. The model likely overpredicts the potential risk from thallium based on detection limits; thallium was detected in relatively few of the canyon bottom samples (37% detection frequency). In addition, thallium was only detected above the BV in five sediment samples in the Mortandad watershed, three in E-1E and 2 in M-2W. This indicates relatively small releases of thallium from the TA-50 RLWTF and low levels of thallium contamination in a small area, as discussed in Section 7.1.2.

Refinement of COPEC Dose to the Shrew from Earthworms

Some COPECs in the ecological screening in the biota investigation work plan had HQs exceeding three for deer mice and for shrews. All deer mouse COPECs were also shrew COPECs. Therefore, the shrew (which has a higher exposure because the diet is modeled as 100% earthworm versus 50% earthworm for the deer mouse) was evaluated through modeling of the dose through earthworms based on estimated concentrations in earthworms. Regression equations or concentrations based on transfer factors from the ECORISK Database Version 2.2 were used, as explained for the avian receptors in Section 8.1.3.3. The results of the calculations are shown in Table 8.1-7. Only thallium has an HQ >3 for the shrew; this would also be the case for the deer mouse. Thallium has a very low TRV for mammals and uses a default transfer factor of one to estimate the concentration in earthworms. Table 8.1-8 provides some additional information on the comparison of thallium HQs between reaches. Because these factors are so conservative, the thallium HQ shown in the table is likely to overestimate risk. As discussed above and in Section 7.1.2, there is also evidence of only very small releases of thallium into the canyon bottoms.

8.1.3.5 Detritivores

The earthworm toxicity tests measured growth and survival of earthworms at seven locations in the Mortandad watershed in comparison with the background location in reach LA-BKG (EP&T 2005, 91267). The results for this test, including all replicates, are summarized with box plots for survival and growth (as weight change) in Figures 8.1-24 and 8.1-25. Negative and positive control samples from the laboratory are also shown (LAEW-Neg and LAEW-Pos). The boxes on these plots indicate the interquartile range of the sample results, with the upper and lower ends defined by the 75th and 25th percentiles, respectively. Horizontal lines within the boxes indicate median values, and lines above and below the boxes represent the 5th and 95th percentiles of the data. Dunnett's t-Test results are presented in the right-hand section of each figure. The comparison circles indicate statistical differences between the tests and the reference site (LA-BKG). The background sample for the Dunnett's t-Test is displayed as a heavy red circle, and the text for the reference site is printed in bold red text on the x-axis. Thin red circles represent samples that are not statistically different ($p < 0.05$), and the reach names for these reaches are in red on the axis. Heavy gray circles represent samples that are statistically different, and these reach names are printed in black on the x-axis. No significant differences in survival were seen between any of the sites and the reference site; survival was almost 100% in all replicates, except the Laboratory positive controls (LAEW-Pos samples). In all treatments, including the negative Laboratory control (LAEW-Neg sample), worms showed weight loss, which is typical of earthworms in this assay (EP&T 2005, 91267). Only one reach, M-2W, showed a significant decrease in weight compared with the reference site in LA-BKG. The composite sediment samples from each reach were also analyzed for COPECs; the concentrations of all earthworm study design COPECs in M-2W were lower than the concentrations of these COPECs in some other reaches that did not have as high a weight loss (Table 8.1-9). The higher weight loss of worms in

the sample from this reach is therefore unlikely to be related to the presence of earthworm COPECs in the soil.

Organic matter in soil can serve as a food source for earthworms during this type of test. The organic matter was measured in each of these samples, but the organic matter in the sample did not correlate with the percent survival or weight change in the test groups (see figures in Appendix E).

8.1.3.6 Plant (Primary Producers)

Seedling Germination and Growth

A number of measures of plant growth and survival are included in the Laboratory toxicity test on samples collected from the Mortandad watershed; these measures include mass of dry shoots, mass of dry roots, mass of wet shoots, mass of wet roots, percent survival, mean root length, and mean shoot length. The complete results are provided in EP&T (2005, 91268). The results are plotted on box plots with the results of the Dunnett's t-Test comparison printed on the right-hand side of the figure; this type of figure is explained in Section 8.1.3.5. As shown in Figure 8.1-26, the dry mass of roots, dry mass of shoots, and mean root length showed no significant differences between reaches, although the test sites did differ from the negative and positive (boric acid) laboratory control samples. In the analysis of wet root length shown in Figure 8.1-27, the plants grown in soil from reach TS-2C had significantly higher mass of wet roots and wet shoots than the other reaches, which were not significantly different from each other. The dry weight of roots and shoots in TS-2C did not differ from the other reaches.

The soil samples used in the plant toxicity test were also analyzed for study design COPECs. The results of those analyses show that reach TS-2C had lower concentrations of chromium, copper, manganese, thallium, vanadium, and zinc than some of the other reaches, although that soil sample had the maximum detected concentration of silver (Table 8.1-9).

Plant survival by reach is shown in Figure 8.1-28. The Dunnett's test results indicate the reaches can be divided into two groups. Reaches E-1W, E-1E, and M-2W represent a group with the highest survival rate. Reaches E-1FW, M-4, TS-1C, TS-2C, and the reference site (LA-BKG) form a second group with slightly lower survival. Although survival in the two groups differ statistically, it is important to note that survival in all replicates from all reaches (except a single replicate from M-4) exceeded 87%, and the background sample was also in the lower survival group. Differences in survival are therefore unlikely to have population level effects and are not related to the presence of COPECs.

Mean shoot length is shown in Figure 8.1-29. The Dunnett's test for this measure also divided the reaches into two groups; these groups did not contain the same reaches as seen in the results for survival discussed above. For the measure of shoot length, reaches E-1E and TS-2C are statistically the same as the reference site (LA-BKG). Reaches E-1FW, E-1W, M-2W, M-4, and TS-1C form a second group with a slightly decreased mean shoot length.

Nutrients in soil can strongly influence growth in soils during this test. Therefore, nutrient parameters such as phosphate, nitrate, and percent organic matter were measured on the soils used in the plant toxicity test. The laboratory negative control sample, for example, contains 10% organic matter, which is the primary reason the control growth always exceeds the growth in the soils from the Laboratory, which are much lower in organic matter. Each growth measure is compared with phosphate, nitrate, and percent organic matter in the bivariate plots in Appendix E. Based on the bivariate plots, percent organic matter may influence plant growth measures in the test regardless of the presence of COPECs in the soil sample.

Abundance and Diversity of Plants

Data from a field survey of plant abundance and diversity in the Mortandad watershed (Balice and Sandoval 2006, 93689) provide supplemental information on plant communities between reaches and possible effects of COPECs on plants. Table 8.1-10 provides the total species richness, the Shannon diversity index for all species, and the total percent canopy cover for all species. These same reaches were surveyed in 2003 for species richness, and the average species richness of 36 from 2005 is much higher than the 2003 species richness of 25. This increase in species richness occurred for all vegetation categories except cacti and is associated with the lessening of drought conditions between surveys. The increase in plant species richness with higher precipitation from one survey year to the next supports the results of the toxicity assay, indicating that COPECs in the canyon soils are not inhibiting the germination or growth of plants in these areas. Part of the variability in species between reaches is caused by variations in climate, including the general increase in annual precipitation from east to west across the study area. Differences in local topography and hydrology, such as canyon width and depth and presence or absence of wetlands, also affect plant communities. Total species richness, Shannon diversity index, and total percent canopy cover for each reach are plotted versus distance from the Rio Grande as a measure of relative precipitation in Figure 8.1-30. The Shannon diversity index has a significant positive correlation with distance from the Rio Grande (primarily caused by diversity at reach LA-BKG representing an outlier value), suggesting that climate is a primary control on this measure. In contrast, total species richness and total percent canopy cover have much variability with distance, which suggests other factors are important. Total species richness is least in reaches M-2W, E-1W, and E-1E, and total percent canopy cover is also least in E-1E at intermediate distances from the Rio Grande. E-1E and M-2W are the narrowest reaches included in this study, bounded by Bandelier Tuff bedrock, and E-1W is the reach with the largest wetland in this study, suggesting that these factors have negatively affected species richness and canopy cover. The presence of COPECs in canyon soils may also potentially affect these parameters, although the results of the toxicity assay indicate that COPECs in the canyon soils are not inhibiting the germination or growth of plants in these areas.

8.1.3.7 Aquatic Community

Chironomus Tentans Toxicity Bioassay

The *Chironomus tentans* toxicity test measures survival and growth of larval insects in active channel sediment collected from the eight reaches specified in Table 8.1-1. A complete description of the test conditions and results is contained in Pacific Ecorisk (2005, 91271). Figure 8.1-31 shows box plots of the number of live larvae remaining per replicate per reach at the conclusion of the test. This box plot shows no significant differences in larval survival between the selected reaches or between the reaches with COPECs and the reference site in reach LA-BKG. Figure 8.1-32 shows the mean dry weight of surviving larvae in each replicate test for each reach. This box plot also shows no significant difference between reaches for this measure of larval growth. Box plots of two other measures of larval growth, total ash-free dry larvae weight and mean ash-free dry larvae weight, are presented in Appendix E. Neither of those growth measures showed any difference between reaches. These results indicate that sediment COPECs do not have an effect on the growth or survival of *C. tentans*.

Rapid Bioassessment Characterization

Data on collected macroinvertebrates, habitat scores, and dissolved oxygen levels in reaches E-1W, M-1W, and M-2W indicate that these sites are marginal for sustaining a diverse community of aquatic life (Henne and Buckley 2006, 93687). However, the assessment protocols used are based on perennial streams and may be biased toward rating ephemeral streams as degraded. Hess sampling could not be

used because of low flow conditions, so quantitative estimates are not available for comparison to the NMED metric. Macroinvertebrates were collected from each reach by D-frame dip net. During both sampling events (June and September 2005), 25% of the taxa at reach E-1W were chironomids. In June, chironomids constituted 85% of the identified individuals from this site as well. Chironomids represented 25% of the taxa and 92% of the individuals in M-1W in June, and 16% of taxa and 71% of individuals in September. The site in reach M-2W also contained predominantly chironomids; chironomids were 33% of the taxa and 69% of individuals in June, and the site was dry in September. The predominance of chironomids at the sites also supports the use of the *Chironomus tentans* Laboratory toxicity test as the appropriate assay to determine if sediment COPECs are adversely impacting the macroinvertebrate communities in these ephemeral stream systems.

Algal Toxicity Test

Water was collected from areas of intermittent or persistent water in reaches E-1W, E-1E, M-1W, M-2W, and LA-BKG in July 2005 for tests of algal toxicity, and from reaches TS-1C, TS-1E, and TS-2C in August 2005 after summer rainstorms provided enough water in these drier reaches. These two sampling events resulted in two separate tests for toxicity of water to algae. For these short-term tests, the endpoint is growth expressed as number of cells versus the control. The results of the toxicity tests are reported in Pacific Ecorisk (2005, 91270). Different rates of growth were seen in the controls between the two tests, so the results for the two tests are shown separately. Figure 8.1-33 shows a box plot comparing the samples from each reach (this type of plot is explained in Section 8.1.3.5) with the July samples, which include the reference site (LA-BKG). Laboratory controls are labeled ”control” and “0.5 ZN” (0.5 ppm zinc as a positive control) through “20 ZN” (20 ppm zinc as a positive control). Figure 8.1-34 shows a box plot for the laboratory controls and samples from Ten Site Canyon collected in August. The box plots show that for both sets of tests, growth in all reaches except TS-1C exceeded both the negative (Laboratory control water) and positive laboratory controls (the range of zinc growth-inhibiting concentrations) for the test.

Table 8.1-11 shows the concentrations of detected radionuclides in algal test samples that are study design COPECs and the value for the algal HQ based on these concentrations. Radium-226 was detected in the M-1W sample, and americium-241 was detected in the E-1E, M-2W, and TS-1C samples. A comparison between Figures 8.1-33 and 8.1-34 and Table 8.1-11 shows that the differences in growth do not correspond to the detected concentrations of radium-226 and americium-241. The only reach sample in which algal growth was inhibited was in TS-1C; this sample contained the lowest detected concentration of americium-241, and radium-226 was not detected in that sample. The growth rates for all reaches were compared with general water quality parameters, which can strongly influence the results of this type of test. For both tests, the mean algal cell density correlates extremely well with water hardness, as shown in the bivariate plots in Figure 8.1-35. These results indicate that differences in the growth rates of algal cells between reaches (including reach TS-1C) result from the differences in water hardness between samples from the reaches and not from the concentrations of radionuclides in the water samples. Bivariate plots of algal cell density against conductivity and alkalinity are presented in Appendix E. None of these parameters correlated with cell growth as well as the water hardness.

The detected concentration of radium-226 in the M-1W sample has an HQ >3 (equivalent to a study design COPEC), but this sample did not show adverse impacts to the growth of green algae when compared with positive controls in the test. The detected concentrations of americium-241 are below the ESL, and the test results do not indicate adverse impacts to populations of green algae.

Estimate of COPEC Dose through Food to the Bat

Although several COPECs in the Mortandad watershed had HQs >3 for the bat (aluminum, arsenic, and naphthalene), the bat was not identified as an appropriate measure for an assessment endpoint in the biota investigation work plan because its large home range and high food ingestion rate indicate that much of a bat's food would be obtained from outside the watershed. However, because nest box insect tissues were analyzed to evaluate avian receptors, these same analytical results were used to refine the potential COPEC dose through food to the occult little brown myotis bat, as shown in Table 8.1-12. Because of the size of the insect samples, only metals analyses could be run on the insects. Therefore, naphthalene was not included in these calculations. Aluminum was included in the analytical suite for the nest box insects, but the ESL for aluminum has been updated to follow EPA guidance that aluminum is only a potential COPEC in soils with a pH below 5.5 (EPA 2003, 85645); therefore, aluminum no longer fits the ESL model for accumulation through the food chain and is also not included in Table 8.1-12. The HQ for arsenic for bioaccumulation through insects into the bat is 0.6, indicating no potential risk to the bat through ingestion of insects even if all insects come from the canyon bottom areas within the Mortandad watershed.

8.1.3.8 Refinement of COPEC Dose to the Fox through Ingestion of Small Mammals

The red fox was not evaluated as the measure for a specific endpoint in this study, but Aroclor-1254, Aroclor-1260, and cesium-137 had HQs greater than 3 for the red fox in the ecological risk screening (LANL 2005, 89308, p. D-35). For the two PCBs, maximum detected concentrations in whole small mammals were used to refine the dose estimate. These calculations and the resulting HQs are shown in Table 8.1-13. Aroclor-1254 and cesium-137 were not detected in small mammal tissues, so this COPEC is not evaluated further. For Aroclor-1260, the maximum whole body concentration was detected in a montane shrew. The calculated HQ for Aroclor-1260 is 0.003, indicating no potential risk to the red fox from PCBs through ingestion of small mammals

8.1.4 Risk Characterization

ERAGS Step 7 is risk characterization, which includes risk estimation and the uncertainty analysis. Risk estimation includes a summary of the results for the measures used to evaluate potential for ecological effects. A qualitative weight of evidence (WOE) criterion was assigned to each measure in Appendix D of the biota investigation work plan (LANL 2005, 89308). If measures indicate different outcomes, meaning one measure indicates a potential for adverse effects and one does not, then the overall conclusion would be weighted toward the measure with the higher WOE.

8.1.4.1 Risk Estimation

Mexican Spotted Owl

The two main measures for the Mexican spotted owl are the ECORSK.9 modeling and the modeling of estimated dose through the food chain from the study design COPECs detected in small mammals. The WOE assigned to each measure is shown in Table 8.1-14. In the ECORSK.9 model, the total adjusted mean HI (using zero for nondetects) across the core and buffer areas for the owl was 1.6. This value exceeds the HI target of 1.0, indicating a small potential for effects to individual owls, primarily from bis(2-ethylhexyl)phthalate (Section 8.1.3.1 and Gonzales et al. 2006, 93786). This SVOC has a high frequency of nondetects in sediment samples from the Mortandad watershed (99.5% nondetects; Section 7.1.3.3), and the potential risk is largely from analyses of samples collected outside the canyon bottoms. One Mexican spotted owl nest currently exists in the Mortandad watershed, and the adjusted HI for this

nest location is 0.2, which does not indicate potential risk to the Mexican spotted owl. The other measure estimated the dose to the Mexican spotted owl based on detected concentrations in mammal tissue (Section 8.1.3.1). The dose modeling was conducted for the nonradionuclide COPECs for the owl (Aroclor-1254, mercury, and selenium) as determined by the screening against ESLs in the biota investigation work plan. The dose modeling shows no HQs greater than 0.5, indicating no potential risk to the owl. Small mammals were not analyzed for SVOCs. Bis(2-ethylhexyl)phthalate was not a study design COPEC in the original screening because it had a higher ESL in the version of the ECORISK Database (Version 2.1, LANL 2004, 87386), which was current at that time. The owl pellet analysis showed that the small mammal species used in the dose modeling are among the species consumed by the Mexican spotted owl in the Mortandad watershed. Based on the dose modeling and on the ECORSK.9 model results for the portion of the canyon in which Mexican spotted owls currently nest, the WOE indicates no adverse effects of COPECs on survival and reproduction of the Mexican spotted owl (AE1).

Southwestern WillowFlycatcher

The aerial insectivores applicable measures for the southwestern willow flycatcher are the ECORSK.9 model, the results of estimated dose through prey using the concentrations of COPECs detected in nest box insects and the field nest box measures. The WOE assigned to each measure is presented in Table 8.1-15. The ECORSK.9 model had a total mean adjusted HI of 6.2, indicating some potential for risk to the flycatcher through exposure to mercury, di-n-butyl phthalate, boron, and bis (2ethylhexyl) phthalate (Section 8.1.3.2 and Gonzales et al. 2006, 93786). The food chain modeling showed HQ values >1 for six metals when the maximum detected concentration in insects was used for the calculation. When the mean detected concentration in the insects is used in the calculations, the HQs are still elevated for mercury (if all the mercury is considered to be in the methylated form), copper, vanadium, and zinc. These calculations indicate potential for risk to flycatchers from ingestion of the nest box insects. The WOE from these measures indicates some potential for adverse effects to survival and reproduction of the southwestern willow flycatcher (AE6) from COPECs in sediment. However, the field measures (nest box studies) of other avian insectivores do not show impacts to nest success, which indicates that the models used for assessing the flycatcher overestimate the potential for ecological risk to avian insectivores. In addition, the southwestern willow flycatcher has not been observed in this part of the Laboratory, so the risk to this species is hypothetical at this time.

Avian Ground Invertevore Feeding Guild

A number of measures were evaluated for the avian ground invertevore feeding guild. The WOE assigned to each measure is provided in Table 8.1-16. ECORSK.9 modeling using the western bluebird indicated a total mean adjusted HI of 1.2, too low to have effects on populations of avian invertevores (Section 8.1.3.3 and Gonzales et al. 2006,93786). Modeling the estimated dose of COPECs to the robin through earthworms was also done, although this analysis had to employ estimated concentrations of COPECs in the earthworms instead of measured concentrations as initially planned. The dose modeling indicates a potential for risk to avian ground invertevores through ingestion of COPECs in earthworms. The primary COPECs are mercury, bis(2-ethylhexyl)phthalate, di-n-butyl phthalate, and Aroclor-1254. A number of field measures of impacts on avian invertevore species were also conducted. The measures of nest success through percent fledged, percent female nestlings, and egg size and thickness show no differences between reaches with and without COPECs. Concentrations of COPECs in eggs do not correlate with sediment concentrations, indicating that uptake into the birds is less than the levels predicted by models, including the dose modeling from earthworms. Field surveys of avian species in Effluent, Mortandad, and Ten Site Canyons did not show any differences in species diversity or avian diet types represented between the canyons, even though di-n-butyl phthalate was a study design COPEC in

Ten Site Canyon and not in Effluent and Mortandad Canyons. Overall, the WOE indicates that COPECs in the Mortandad watershed do not pose a risk to population abundance or persistence and species diversity of avian ground invertevore feeding guild species (AE2).

Mammalian Invertevore and Omnivore Feeding Guild

The mammalian invertevore and omnivore feeding guild includes both the deer mouse (an omnivore) and the shrew (an insectivore). Four lines of evidence were evaluated for these species, and the WOE for these lines is presented in Table 8.1-17. The unadjusted HI had only thallium as a COPEC; this results because thallium has a low TRV and the data set consisted mostly of nondetects that elevated the HQs. ECORSK.9 modeling for the deer mouse showed no COPECs with the adjustment to remove the contribution of thallium (Section 8.1.3.4 and Gonzales et al. 2006, 93786). The tissue and pelt concentrations of COPECs were measured in small mammals as well. This line of evidence was primarily for dose modeling to receptors that eat small mammals, but the results are also relevant to the small mammals themselves. Very few of the COPECs detected in the small mammals correlated with the concentrations in sediment: three COPECs correlated with body tissue, two with pelt, and two with whole animals. These results indicate that the ESL model overestimates the uptake of COPECs into small mammals. Thallium was one of the COPECs that did not correlate with soil concentrations in any of the tissues tested.

The third measure for the small mammals was to estimate the potential dose to them through ingestion of earthworms. As with the avian receptors, estimated COPEC concentrations in earthworms had to be substituted for the planned analytical results. Both the shrew and deer mouse are modeled for the ESL development with invertebrates in their diet, but as explained in Section 8.1.3, the dose modeling was conducted using the shrew. Only thallium had an HQ >3 for the small mammals; this results because thallium has a low TRV and a default transfer factor of 1. Thallium in earthworms did not correlate with soil concentrations of thallium in the study in the Los Alamos and Pueblo watershed; therefore, the thallium result from the modeling is likely to greatly exceed the actual risk and not be a strong line of evidence for small mammals. Overall, the WOE for small animals indicates that COPECs in soil do not have adverse effects on population abundance or persistence and diversity of mammalian invertevore and omnivore feeding guild species (AE3).

Mammalian Carnivore Feeding Guild

Although the fox did not represent a specific assessment endpoint because carnivores were evaluated through AE1, the ecological screening presented in the biota investigation work plan indicated that PCBs may impact this receptor. The mammal tissue concentrations of PCBs were used to calculate a refined estimate of dose through the food chain (Section 8.1.3.8). Only Aroclor-1260 was detected in small mammal tissue and the HQ for Aroclor-1260 was less then 0.01, indicating that there is no risk to this receptor through ingestion of small mammals in the Mortandad watershed.

Detritivores

ALaboratory toxicity test measured both survival and weight change in earthworms from samples in reaches with and without soil COPECs (Section 8.1.3.5). The WOE for this measure and measures of detritivores relevant to other receptors is given in Table 8.1-18. There was no difference in survival between any of the reaches. There were differences in weight loss between the reaches, but the differences in weight loss did not correlate with COPEC concentration. The WOE for detritivores indicates that COPECs in soil in the Mortandad watershed do not adversely impact survival and growth of detritivore species (AE4).

Plants (Primary Producers)

Lines of evidence and their WOE for plants are provided in Table 8.1-19. The main line of evidence is the seedling germination test with supporting information from the field survey of plants in reaches with different concentrations of COPECs. Survival and most measures of growth in roots and shoots showed no difference between reaches (Section 8.1.3.6). Two measures (wet root length and mean shoot length) differed between reaches but did not correlate with COPEC concentration. The field survey of plants showed no differences between reaches that could be directly related to variations in COPEC concentrations, and all reaches that had been previously surveyed had more species diversity than previously, supporting the finding that germination and growth are not inhibited. The overall WOE indicates no adverse effects of COPECs in soil on native plant species presence and diversity (AE5).

Aquatic Community

The measures used as lines of evidence for evaluating impacts to the aquatic community in the Mortandad watershed, and the WOE assigned to each measure are provided in Table 8.1-20. The Laboratory toxicity test using *C. tentans* showed no difference in survival and no difference in growth correlated with COPEC concentration. The field bioassessment characterization indicated that chironomids dominate the aquatic community in sampled reaches and that the toxicity test using chironomids is therefore an appropriate measure of impacts to the aquatic community. The Laboratory algal toxicity test showed differences in cell growth with reaches, but these differences were attributable to water hardness and not to COPECs in water. The WOE for measures of the aquatic community indicates there are no adverse effects from COPECs in sediment and water on abundance and survival of the aquatic community in the reaches of the Mortandad watershed (AE7).

8.1.4.2 Uncertainty Analysis

Exposure Uncertainty

Uncertainties in the ecological risk assessment are potentially associated with the characterization for sediment and surface water. Maximum detected concentrations were used for some comparisons, which would overestimate the exposure concentration in a reach. For comparisons to bird boxes, arithmetic mean concentrations in soil in each reach were used for comparison; because sampling is biased towardlocations where contaminant concentrations are highest, use of straight means generally provide overestimates of actual exposure concentrations, as discussed in Section B-1.0 of Appendix B. Media concentrations for evaluating the results of Laboratory toxicity tests came from the actual water and sediment samples used in those tests and provide a good estimate of the exposure concentration for the assay organisms. These concentrations would overestimate exposure concentrations throughout the sampled reaches because sampling was biased to specific locations with higher concentrations of COPECs in these reaches. For the small mammal trapping, composite soil samples for comparison were obtained from the traps within the array.This provides a good representation of the concentration in the trapping array, but because the arrays were centered in areas with contaminated sediment deposits, the data are expected to overestimate exposure concentrations for mammals that largely forage outside these areas.

Another uncertainty is the adequacy of the toxicity and bioaccumulation data used to develop the assessment endpoints and select the associated measures and develop the study design. In fact, a number of toxicity values and transfer factors in the ECORISK database and the associated food chain and ECORSK.9 modeling were changed between the design of the studies and their evaluation in this investigation report. These changes brought new COPECs into consideration. Gaps also exist for toxicity

for some classes of COPECs on some receptors that hamper evaluating those COPEC-receptor combinations except in the field studies. The study design included field, Laboratory, and model components to provide complementary information and reduce uncertainties related to toxicity and bioaccumulation data.

Field Measures

Empirical ecological effects data are the most relevant data for determining if there are adverse effects on ecological receptors, especially at the population level. However, these data are inherently more variable and difficult to quantify than laboratory measures. Uncertainty associated with a limited number of locations and a limited number of sampling events is mitigated by collecting information across a variety of measures of exposure and effect.Factors unrelated to COPECs, such as drought and other climatic variations, fire, and annual variation in species, can have confounding effects on analysis of field measures.

Field measures can also provide some information on adverse effects that cannot be obtained with other methods. This includes an estimate of impacts from COPECs for which there are not toxicity values. Field measures also provide valuable information on the usefulness of models and transfer factors in predicting ecological effects.

Laboratory Measures

Laboratory toxicity tests provide more standardized results than field data because they are conducted under controlled conditions, but they are still subject to uncertainties associated with sample collection and representativeness. Confounding factors are also possible, as was demonstrated in this investigation by the effect of water hardness on the results of the algal toxicity test (Section 8.1.3.7). Other confounding factors may include variability in the test species selected; for example, the yarrow used in the plant toxicity test for these studies is more variable in growth than standard assay plants, but it is also more relevant to the ecosystems under consideration. Mortandad watershed soils are generally nutrient-poor, which can influence growth in plant, earthworm, algae, and chironomid tests. Sample sites were also selected to represent a gradient of COPEC concentrations to improve the representativeness of the toxicity tests to potential COPEC impacts.

Model Measures

ECORSK.9 represents a modified exposure model with many of the limitations of the simple exposure models used of screening-level ecological risk assessments. ECORSK.9 blends more realistic information on spatial use of the watershed with simple models of contaminant bioaccumulation and toxicity (Gonzales et al. 2006, 93786). In ECORSK.9, conservatism is still present for key parameters like TRVs and bioaccumulation factors. For example, the TRVs are based on NOAELs or the geometric mean of NOAEL values, and risks are assessed assuming additivity of response or summing of exposure across COPECs. ECORSK.9 is also based on conservative estimates of COPEC concentrations in soil; it assumes that the average of the sample data for a model grid cell is representative of the true concentration, although sampling is typically biased toward areas with higher concentrations of contaminants (Section B-1.0 of Appendix B). For this study, nondetected concentrations of organic chemicals were handled as either one-half their detection limits or as zero.The different results demonstrate that assumptions regarding nondetects can obscure sources of problem contaminants and overestimate risks. The simple dose modeling from concentrations in food done for this investigation is subject to many of the same uncertainties arising from toxicity values, transfer factors, and assumptions about concentrations and nondetects as the ECORSK.9 modeling.

8.1.5 Summary

Many COPECs were identified as study design COPECs in the ecological screening of soil, sediment, and surface water in the Mortandad watershed. The WOE demonstrated by the various lines of evidence for the seven assessment endpoints indicates there are no adverse effects of COPECs on terrestrial and aquatic receptors in the Mortandad watershed. The overall WOE from field studies, analysis of COPEC concentrations in tissues, and Laboratory toxicity tests supports this conclusion. Some of the results from modeling (both ECORSK.9 modeling and the dose through food ingestion modeling) indicate a potential for some ecological risk. However, these two models incorporate many of the same conservative factors (TRVs and transfer factors) inherent to the original screening using ESLs, which are designed to overestimate potential effects to provide a conservative screen. Therefore these models are not as strong a line of evidence as the other studies mentioned. Thus, no COPECs are retained for any further assessment or mitigation as a result of this baseline ecological risk assessment.

8.2 Human Health Risk Assessment

This human health risk assessment evaluates the potential for adverse effect on human health in the Mortandad watershed for COPCs identified in Section 6 of this report. The risk assessment approach used in this report follows guidance from EPA (1989, 08021), LANL (2004, 87800), NMED (2006, 92513), and EPA (2005, 91002) and is organized in seven major subsections. The approach utilizes media- and scenario-specific media-based screening levels to evaluate the potential for human health risks from sediment and surface water in the Mortandad watershed. Section 8.2.1 provides the basis for selecting exposure scenarios for the human health risk assessment. In Section 8.2.2, the data collection and evaluation processes described in previous sections of the report are summarized, focusing on aspects of data analysis that are pertinent to the risk assessment. Section 8.2.2 also lays out the logic for selecting COPCs for the human health risk assessment. The exposure assessment (Section 8.2.3) provides information used in quantifying human exposure to COPCs in sediments and water. The toxicity assessment (Section 8.2.4) provides information on potential human health effects from chemicals and radionuclides evaluated in the risk assessment. Section 8.2.4 provides the sources for the media- and scenario-specific screening levels. Risk characterization (Section 8.2.5) is based on the SOF method for evaluating the potential for additive effects with COPCs that are classified as noncarcinogens, carcinogens, or radionuclides. Uncertainty related to the various assumptions and inputs used in the risk assessment is evaluated in Section 8.2.6 to support interpretation of the risk characterization. A summary of the risk assessment is provided in Section 8.2.7.

8.2.1 Problem Formulation

The purpose of this risk assessment is to evaluate potential human health risks related to the COPCs identified in sediments and surface water in the Mortandad watershed. This information can be used to inform a risk management decision. This risk assessment uses information pertaining to current and reasonably foreseeable future land use to assess potential impacts under reasonable maximum exposure (RME) conditions. The canyon bottoms in the Mortandad watershed include a mixture of Laboratory property and San Ildefonso Pueblo lands, potentially supporting a variety of land use alternatives.

The assessment in this report primarily employs the trail user exposure scenario to represent the current and reasonably foreseeable future exposure activities for contaminated sediments and surface waters in the watershed. The trail user scenario describes an adult individual who contacts contaminated sediments and surface water while hiking or jogging in the canyons. This use is considered to be inclusive of realistic present-day potential exposure activities in canyon bottoms in areas of the watershed where contaminants are at levels requiring a human health risk assessment.

One supplemental exposure scenario, residential, is evaluated in the human health risk assessment for comparison purposes only. A description of this supplemental exposure scenario is provided in Section 8.2.3.3. Unlike the trail user scenario, residential use is not currently applicable across the watershed. A residential scenario does not represent current or reasonably foreseeable future land uses in the canyon bottoms, and residential development in particular is not a feasible land use within the parts of the canyons subject to flooding.

Assessment results for the trail user scenario are provided in Section 8.2.5. The results of risk calculations for the residential scenario are provided in Section E-3 of Appendix E.

8.2.2 Data Collection and Evaluation

The approach to sampling design, data collection, and characterization is described in Sections 3 and 4 and Appendix B. Sample locations, sample results, and data quality for data employed in the human health risk assessment are presented in Appendix C. Section 6 describes how sediment data were separated into reaches and status and how sediment data within reaches were combined for the comparison of contaminant data maxima with BVs. Water data were evaluated at each surface water sampling location, as described in Section 6.

Identifying COPCs for the Human Health Risk Assessment

COPCs for the human health risk assessment are identified based on screening level risk calculations using a residential exposure scenario. This process is initially inclusive of all COPCs and evaluates the potential for human health risks under a protective residential scenario. This process includes calculating a ratio, which is the maximum concentration of an analyte in a specific media in a reach or at a water sampling station divided by the media-specific risk-based screening level. This is analogous to the HQ as used in Section 8.1 for assessing potential ecological risk. An SOF is also calculated for a risk type; i.e., carcinogens (SOF_{ca}), noncarcinogens (SOF_{nc}), and radionuclides (SOF_{rad}). These are analogous to HIs calculated in Section 8.1. Ratios for all COPCs within a reach or water location are summed to calculate the SOF for the risk class of those analytes (carcinogen, noncarcinogen, or radionuclide). For all reaches or water locations with an SOF >1.0 for a risk class, all COPCs within that risk class with ratios greater than 0.1 are retained as COPCs for the site-specific risk assessment. COPCs with a ratio ≤0.1 based on maximum sample results are excluded because they are unlikely to significantly contribute to risk.

Sediment COPCs: The human health screening levels for nonradionuclides in sediment used in this screening assessment are the NMED residential SSLs from Revision 4 of NMED guidance (NMED 2006, 92513). For analytes for which NMED does not provide a value, the residential screening value from EPA Region 6 (EPA 2005, 91002) or EPA Region 9 (epa.gov/region09/waste/sfund/prg/files/04prgtable.pdf) was used as the SSL (carcinogens are adjusted to a 10^{-5} risk level to be consistent with the NMED target risk level). NMED-approved surrogate compounds were used for some COPCs that lack NMED or EPA screening levels (NMED 2003, 81172). SALs related to residential land use for radionuclides are based on the soil guidelines for unrestricted release of property (DOE Order 5400.5, “Radiation Protection of the Public and the Environment”); these values are derived using RESRAD version 6.21 as described in “Derivation and Use of Radionuclide Screening Action Levels Revision 1” (LANL 2005, 88493).

Tables 8.2-1 to 8.2-3 contain the set of human health residential SSLs and SALs used to calculate ratios; these tables also provides the SOFs for each reach for each risk class for all sediment COPCs. COPCs and reaches shaded gray are those retained for the risk assessment. Table 8.2-1 provides the results for noncarcinogens, Table 8.2-2 provides the results for carcinogens, and Table 8.2-3 provides the results for radionuclides.

Surface Water COPCs: Screening levels for surface water for organic and inorganic chemicals are the EPA Region 6 risk-based screening levels for tap water (EPA 2005, 91002). The EPA Region 6 values were supplemented by screening values from EPA Region 9 , available at (epa.gov/region09/waste/sfund/prg/files/04prgtable.pdf). Radionuclide screening levels are based on a dose of 4 mrem/yr and are from the DOE DCG (DOE Order 5400.5, "Radiation Protection of the Public and the Environment").

Tables 8.2-4 to 8.2-6 contain the set of human health water screening levels used to calculate ratios; these tables also provide the SOFs for each type of field preparation (filtered or unfiltered) for each water location, and each risk class for all surface water COPCs. COPCs and water locations shaded gray are those retained for the further assessment. Table 8.2-4 provides the results for noncarcinogens; Table 8.2-5 provides the results for carcinogens; Table 8.2-6 provides the results for radionuclides. Surface water data have been obtained from the surveillance station "Mortandad at Rio Grande" (monitoring station A-11), and there is no associated reach for this location. The primary source of surface water at station A-11 is effluent from the Los Alamos County wastewater treatment plant in White Rock. The SOF_{nc} for station A-11 was 1.01, and the primary contributors to the sum were fluoride and vanadium. Because station A-11 has no associated sediment sample results, and surface water is wastewater effluent, this location will not be retained for evaluation in the human health risk assessment.

COPC Summary: Table 8.2-7 presents a summary of endpoints and reaches considered in the human health risk assessment for the Mortandad watershed. For each reach and endpoint combination with both sediment and water COPCs retained, a multimedia assessment is also assessed for this reach. Table 8.2-7 shows that the most downstream reach in the Mortandad watershed requiring further human health risk assessment is reach M-4.

Calculating Representative Concentrations

Sediment: The investigation approach for sediments resulted in samples associated with discrete geomorphic units and sediment facies within each reach. These data are combined to estimate weighted averages and weighted 95% upper confidence limits (UCLs) on the averages for COPCs retained for the human health risk assessment in each reach. The approach to estimating weighted averages and weighted 95% UCLs is well established in the statistical methods for stratified sampling, (e.g., Gilbert 1987, 56179; Cochran 1977, 84462). A description of these methods is provided in Section E-3 of Appendix E. Many of the data sets for combinations of COPCs and reaches or COPCs and water sampling locations include nondetect values. The approach to estimating averages and 95% UCLs with data that include nondetects is also described in Section E-3 (Appendix E).

The trail user exposure scenario uses representative sediment concentrations calculated from surface-area weighted averages and surface-area weighted 95% UCLs for sediment facies that typically occur in the uppermost parts of geomorphic units because trail user exposures predominantly occurs with near-surface sediment. In addition, the uppermost sediment facies is usually finer grained and contains higher contaminant concentrations than deeper sediment, thus providing a more protective assessment. The calculation approach for the averages and 95% UCLs uses the relative areas of the different geomorphic units in a reach to derive the weights. The residential exposure scenario includes activities that penetrate the ground surface, resulting in direct exposure to buried sediments. Therefore, the residential exposure scenario uses the volumes of sediment deposits within geomorphic units to derive weights rather than the surface areas. The area weights and volume weights for each unit in each reach are presented in Table D-1.3-1 in Appendix D. Representative sediment concentrations for the trail user scenario are presented in Section 8.2.5.

Surface Water: Water COPC concentrations are evaluated for each sampling location, unlike sediments where multiple sample locations are combined to generate a representative concentration for a reach. The only exception is for locations that are basically collocated within a few meters of each other. As a result, methods to estimate weighted averages and weighted 95% UCLs are not used to calculate water representative concentration. The approach to calculating averages and 95% UCLs for the water data follows the approach described in Section E-3 (Appendix E). Representative surface water concentrations for the trail user scenario are presented in Section 8.2.5.

8.2.3 Exposure Assessment

The trail user scenario is the exposure scenario that applies to all reaches identified in Table 8.2-3. Additionally, potential risk associated with the residential scenario is provided as a point of comparison. The two exposure scenarios employed in the human health risk assessment have been described in other documents. The trail user scenario is the adult receptor in the recreational scenario document (LANL 2004, 87800) and the recreational scenario in the radionuclide SALs document (LANL 2005, 88493). An adult trail user is evaluated in this assessment because access to these reaches is limited to Laboratory workers or trespassers, and it is unlikely that young children would accompany either workers or trespassers on recreational visits to these reaches. Exposures to surface water ingestion are evaluated based on the trail user scenario described in the "Los Alamos and Pueblo Canyon Investigation Report" (LANL 2004, 87390, p. 8-37), which also provides risk-based concentrations for trail user surface water exposures (LANL 2004, 87390, p. E-317). Residential SSLs are in NMED guidance (NMED 2006, 92513), and residential SALs are in LANL guidance (LANL 2005, 88493).

8.2.3.1 Exposure Scenario Description

The human health risk assessment focuses on potential risks resulting from direct exposure to contaminants in sediments through ingestion, inhalation, external irradiation (radionuclides only), and dermal contact (chemicals only). The water pathways for the trail user consist of ingestion and dermal contact (chemicals only) using persistent surface water data. Exposure to stormwater is not assessed because stormwater is transient and does not occur frequently enough to sustain chronic exposures. Exposure to groundwater is not evaluated because no groundwater in the Mortandad watershed is available for human uses under current conditions or for the reasonably foreseeable future. A summary of potentially complete exposure pathways, by scenario, is provided in Table 8.2-8.

Exposure scenario parameters were selected to provide an RME estimate of potential exposures. As discussed in EPA (1989, 8021), the RME estimate is generally the principal basis for evaluating potential health impacts. In general, an RME estimate of risk is at the high end of a risk distribution, i.e., 90th–99.9th percentiles (EPA 2001, 85534). An RME scenario assesses risk to individuals whose behavioral characteristics may result in much higher potential exposure than seen in the average individual.

The trail user scenario addresses limited site use for outdoor activities such as hiking and jogging. The receptor for this scenario is anticipated to be a Laboratory employee using the canyon over an extended period of time. Therefore, receptors for the trail user scenario are defined as adults. A complete description of the parameter values and associated rationale is provided in Laboratory guidance (LANL 2004, 87390, p. 8-37). Exposure parameters for the trail user are provided in Appendix E-3.

8.2.3.2 Supplemental Exposure Scenario

Risk estimates are provided for a resident as a supplemental exposure scenario. A more detailed discussion of the basis and parameterization of this scenario is provided in NMED guidance (2006,

92513) and Laboratory guidance (LANL 2005, 88493). Exposure parameters for the resident are provided in Appendix E-3.

8.2.3.3 Spatial Scales of Application for the Exposure Scenarios

Each exposure scenario is evaluated at the scale of a reach for sediments and at the scale of individual sampling locations for water. Each of the surface water sampling locations has been associated with a reach for combining results into a multimedia assessment (where appropriate). The investigations evaluated in this report have multiple investigation reaches and water sampling locations. The risk assessment does not attempt to integrate exposure across multiple reaches for sediment or across water sampling locations for surface water. By assessing each reach and associated water sampling locations separately, the impacts of local variability in COPC concentrations upon the risk assessment results are preserved.

8.2.4 Toxicity Assessment

This section of the human health risk assessment provides information related to the basis for distinguishing among the three classes of chemicals that are evaluated in this assessment: systemic toxicants (noncarcinogens), chemical carcinogens, and radionuclides. This information provides a context for interpreting the results of the risk assessment, which employs COPC-specific values of toxicity and radiation dose to evaluate potential health impacts.

Using media-specific risk-based screening levels simplifies aspects of the risk assessment in that exposure and toxicity information has been compiled in available guidance documents and reports. The sources for toxicity data used for this risk assessment include NMED and LANL guidance documents and the "Los Alamos and Pueblo Canyon Investigation Report" (LANL 2004, 87390) and its supplement (LANL 2005, 91918). The "Los Alamos and Pueblo Canyon Investigation Report" is used as a source of surface water screening values because there is no guidance document available with such values, and the exposure information provided therein is germane to trail user exposures in other Laboratory canyons. Toxicity information used to develop surface water screening values is also generally consistent with values used in NMED and LANL guidance documents (as discussed below).

Media-specific risk-based screening levels are from seven sources based on COPC type and exposure medium.

- Recreational scenario (trail user) for carcinogens and noncarcinogens
    - Sediment: used the recreational SSLs developed in Laboratory guidance (LANL 2004, 87800)
    - Surface water: used the risk-based concentrations for trail user surface water ingestion and dermal contact developed in the "Los Alamos and Pueblo Canyon Investigation Report" (LANL 2004, 87390, except lead is from LANL 2005, 91918)
- Recreational scenario (trail user) for radionuclides
    - Sediment: used the recreational SALs developed in Laboratory guidance (LANL 2005, 88493)
    - Surface water: used the risk-based concentrations for trail user surface water ingestion developed in the "Los Alamos and Pueblo Canyon Investigation Report" (LANL 2004, 87390)

- Residential scenario for carcinogens and noncarcinogens
    - Sediment: used the SSLs from NMED guidance (NMED 2006, 92513), except for certain values from EPA Region 6 (EPA 2005, 91002) and EPA Region 9 (epa.gov/region09/waste/sfund/prg/files/04prgtable.pdf)
- Residential scenario for radionuclides
    - Sediment: used the residential SALs developed in Laboratory guidance (LANL 2005, 88493)

Table 8.2-9 provides the compilation of the sediment and surface water media-specific risk-based screening levels and target adverse effect-levels. Comparing the screening values with COPCs for a given risk endpoint provides some information of the relative toxicity of these analytes. Because these risk-based screening values are obtained from references prepared from 2004 to 2006, there is potential for differences in the toxicity values used in the screening level calculations. The slope factors and reference doses were compared with the COPCs listed in Table 8.2-9 among the sources; differences in these toxicity values are summarized in Table 8.2-10. This information will be considered in the uncertainty analysis of this assessment.

8.2.5 Risk Characterization

In this section of the human health risk assessment, information provided in the exposure and toxicity assessments (Sections 8.2.3 and 8.2.4, respectively) is integrated to characterize potential adverse effects. The risk characterization is conducted on the basis of the general principles described in Section 8.0 of the risk assessment guidance for Superfund (EPA 1989, 8021). Potential adverse effects related to noncarcinogens, chemical carcinogens, and radionuclides are discussed in Sections 8.2.5.1, 8.2.5.2, and 8.2.5.3, respectively. The presentation of potential adverse effects focuses on the quantitative expressions of potential impacts. In the uncertainty analysis (Section 8.2.6), the confidence associated with the quantitative risk estimates is discussed through an evaluation of the uncertainties pertaining to each step of the risk assessment process.

This risk assessment employs media-specific risk-based screening levels to evaluate COPCs for potential adverse health effects. COPC intake and toxicity are combined within the screening value calculations; therefore, separate calculations of intake and health effects (cancer risk, hazard, and dose) were not generated. Human health effects were assessed using the ratios of representative concentrations to media-specific risk-based screening levels for each COPC retained in this assessment for each of the exposure scenarios. These ratios were summed for an investigation reach and (when applicable) a water sampling location within the COPC classes of chemical carcinogens, noncarcinogens, and radionuclides (SOFs). A sum of less than 1 indicates that exposure is unlikely to result in an unacceptable cancer risk, hazard, or radiation dose. The SOF values were multiplied by the target effect level (i.e., HI = 1, risk = 1×10^{-5}, or dose = 15 mrem/yr) to provide risk estimates for each COPC class.

For the trail user scenario, exposure to sediment and surface water is evaluated through a multimedia sum. For COPCs with a common target adverse effect level (e.g., all carcinogens are based on 1×10^{-5} incremental cancer risk), the multimedia sum can be converted into an approximate effect level. Carcinogen and noncarcinogen screening levels are based on a common adverse effect level across sediment and surface water, but the radionuclide adverse effect levels are not the same for sediment (15 mrem/yr) and surface water (4 mrem/yr).

The trail user scenario multimedia sums and the risk values for noncarcinogens, carcinogens, and radionuclides based on 95% UCLs are summarized in Table 8.2-11. Most of the carcinogen and

radionuclide multimedia sums are similar to the sediment risk values, which indicate that there is greater potential for effects from the sediment concentrations and exposure pathways than from surface water. For noncarcinogens, this observation is reversed for many reaches: the multimedia sum is similar to the surface water risk values. There is one reach where the multimedia sum and the sediment risk values are greater than the target risk level for the trail user scenario: radionuclide dose in reach E-1E.

Table 8.2-12 presents the COPC and reach-specific recreational risk values for sediment; Table 8.2-13 presents the COPC and reach-specific recreational risk values for surface water. The representative concentrations for sediment are presented in Table 8.2-14; the representative concentrations for surface water are presented in Table 8.2-15. Results for the supplemental exposure scenario (residential) are provided in Tables E-3.5-2 and E-3.5-3.

8.2.5.1 Noncarcinogenic Effects

Chemical hazard for an individual chemical is commonly defined by the HQ, which is calculated as the ratio of the chemical intake to the reference dose (RfD) for that chemical. An HQ greater than 1 is indicative of the potential for adverse effects; therefore, an HQ of 1 was used in the calculation of screening values for noncarcinogenic effects. When the potentially additive effects of two or more chemicals are considered, HQs may be summed to generate an HI. However, summing of chemical HQs to create an HI assumes that the target organs and mechanisms of toxicity are similar. The SOF_{nc} values in this human health risk assessment are functionally equivalent to generating an HI. The protective approach of summing these ratios does not warrant refinement because the HI values are in all cases well below 1.0.

The four largest HI values for the trail user scenario were between 0.4 and 0.7 (Table 8.2-11) and related mostly to the potential for adverse effects from lead in surface water (reaches M-1W and TS-1C; Table 8.2-13) or aluminum and iron in sediment (reaches M-1E and E-1FW; Table 8.2-13). The HI was between 0.1 and 0.4 in four other reaches (E-1W, E-1E, M-2W, and TS-2E) with the key contributors to these noncarcinogenic sums being aluminum, arsenic, iron, and manganese in sediment and lead and perchlorate in surface water.

8.2.5.2 Carcinogenic Effects

Cancer risk for an individual chemical is defined by the incremental cancer risk (ICR), which is calculated as the product of exposure to a single chemical and the cancer slope factor (SF) for that chemical. ICRs for each exposure route and chemical are then summed to calculate the total ICR to an individual. A target risk level of 1×10^{-5} was used in this human health risk assessment to calculate risk-based concentrations for carcinogenic effects (NMED 2006, 92513). Lifetime cancer risk is considered to be additive over time; childhood and adulthood exposures are summed to calculate the ICR.

The potential risk from carcinogens was evaluated in 12 investigation reaches, and the range of sediment or multimedia ICR for the trail user scenario was from 8×10^{-7} to 6×10^{-6} (Table 8.2-7). The maximum ICR (6×10^{-6}) was calculated for reach M-1W. The primary contributors to the ICR in these reaches from sediment were arsenic and PAHs (Table 8.2-12). Carcinogenic COPCs were not significant contributors to the ICR for trail users from surface water exposure.

8.2.5.3 Radiation Dose

The radiation dose associated with the EPA dose conversion factors (DCFs) used in the human health risk assessment is the annual committed effective dose equivalent (internal) or annual effective dose

equivalent (external), expressed in units of millirems per year. The target dose limit used for calculating media-specific risk-based screening levels related to soil pathways is 15 mrem/yr, which is consistent with guidance from DOE (DOE-AL 2000, 67153). For water-based exposure pathways, media-specific risk-based screening levels were calculated using a target dose limit of 4 mrem/yr. Use of this more protective dose limit for water pathways is based on the radiation dose limit for a public drinking water supply in DOE Order 5400.5, "Radiation Protection of the Public and the Environment." Consistent with EPA guidance (EPA 1989, 8021), dose through dermal absorption is not quantified because it is probably negligible compared with the other exposure pathways.

The potential risk from radionuclides in sediment was evaluated in 12 reaches; the potential risk from radionuclides in surface water was evaluated in four reaches, and multimedia sums were also calculated in these four reaches. The range of sediment or multimedia radionuclide dose was from 0.01 to 44 mrem/yr; the range of surface water radionuclide dose was from 0.04 to 0.3 mrem/yr (Table 8.2-11). One reach had a radionuclide dose value for the trail user scenario greater than 15 mrem/yr: reach E-1E had a multimedia dose of 44 mrem/yr. Americium-241, cesium-137, plutonium-238, and plutonium-239,240 contributed more than 99% of the dose from radionuclide sediment COPCs for all reaches except TS-1C (Table 8.2-8). In reach TS-1C, thorium-228, thorium-230, and thorium-232 contributed approximately 59% of the radionuclide dose from sediment. Approximately 80% of the dose in reach E-1E from sediment was from cesium-137.

8.2.6 Uncertainty Analysis

The uncertainty analysis uses qualitative and semiquantitative information to evaluate the uncertainty associated with the risk, hazard, and dose estimates described in Section 8.2.5. This uncertainty analysis pertains to the results of the trail user scenario. The uncertainty analysis is organized according to the major aspects of the human health risk assessment: data collection and evaluation (Section 8.2.6.1), exposure assessment (Section 8.2.6.2), and toxicity assessment (Section 8.2.6.3).

8.2.6.1 Data Collection and Evaluation

All analytes that were identified as COPCs in Section 6 were retained for evaluation in the human health risk assessment. COPCs that were retained for calculation of representative concentrations were those that had ratios greater than 0.1 for endpoints with SOF values greater than 1 for the residential screen. Thus, the analytes retained represent an inclusive list of potential human health risk drivers.

No BVs are available for surface water. The inability to distinguish COPCs in surface water based on comparisons with background concentrations is a substantial source of uncertainty in the results of the human health risk assessment for this media. For example, concentrations of arsenic and iron in surface water, which contribute to HI, could be associated with local background and not with releases from Laboratory SWMUs or AOCs.

Overestimating representative concentrations for investigation reaches is another potential source of uncertainty. Five approaches were used to minimize that possibility. First, the emphasis of the geomorphic characterization and sediment sampling was to identify and sample post-1942 sediment deposits, which focuses sampling on potentially contaminated areas. The process of characterizing reaches and focusing sampling is discussed further in Section 4.1 and Section B-1 of Appendix B. Second, the canyon bottoms include other geomorphic units that are not impacted or are only minimally impacted by Laboratory releases. Samples from these other geomorphic units were not included in the area-weighted and volume-weighted averages to provide more protective estimates of COPC concentrations for use in the human health risk assessment. Third, 95% UCLs on the area-weighted

average sediment concentrations were employed as representative concentrations to minimize the chance of underestimating representative concentrations in a reach. Fourth, it was assumed that exposure in most geomorphic units for the trail user scenario was entirely caused by fine facies sediment deposits where concentrations are generally highest, as discussed in Section 7.1, excluding data from coarse facies sediment deposits where concentrations are generally lower. Fifth, for radionuclides, no correction was made for radioactive decay since the time of sampling, although present-day concentrations are lower than at the time of sampling for some key radionuclides. For example, the maximum concentration of cesium-137 measured in the Mortandad watershed was in a sample collected from reach E-1E in 1998, and concentrations in 2006 when this report was written would be about 17% lower in that sediment layer due to radioactive decay. Accounting for radiological decay would decrease the calculated dose in reach E-1E from 44 mrem/yr to approximately 38 mrem/yr.

A similar uncertainty exists for estimating representative concentrations for water sampling locations. COPC concentrations often change with hydrologic conditions and can either increase or decrease seasonally or related to effluent discharges. The data evaluated in this assessment represent a snapshot of the current hydrological conditions and generally reflects a range of hydrologic conditions at each sampling location. As discussed in Section 7.2.1 and Appendix B, Section B-2, sampling occurred during a range of water-level conditions and field parameters, such as pH and dissolved oxygen. The representative concentrations calculated from these data represent the range of COPC concentrations at the sampling locations. Using the 95% UCL on the average minimizes the chance of underestimating the representative concentrations for a sampling location.

8.2.6.2 Exposure Assessment

Uncertainty pertaining to exposure parameters was addressed in the human health risk assessment by using RME estimates for several exposure parameters (see Appendix E-3). The use of RME assumptions, coupled with upper-bound estimates of the average concentration of COPCs in sediment, is intended to produce a protective bias in the risk calculations. The results of the risk assessment, discussed in Section 8.2.5, include a description of the key COPCs and exposure pathways associated with potential health impacts. This evaluation of uncertainty in exposure is focused on these COPCs and pathways.

Key exposure pathways for contaminated sediments across hazard, ICR, and dose for the trail user exposure scenario include dermal absorption, incidental soil ingestion, and external irradiation. A common source of protective bias in the exposure assessment for these pathways is that the entire 1-h daily exposure time defined for the trail user scenario is spent on contaminated sediment deposits within a reach. To the extent that time may be spent in other canyon areas such as uncontaminated stream terraces, colluvial slopes, or bedrock areas during recreational activities, exposure to contaminated sediment deposits is overestimated.

The assessment also includes no consideration of the current signage in the canyon, which reads “No Trespassing: Access to Mortandad Canyon is Restricted to Workers on Official Business.” In addition, the area at the head of reach E-1E at the TA-50 RLWTF outfall is posted as “Caution: Soil Contamination Area.” Because each reach is treated equally from an exposure perspective, no consideration is made regarding ease of access or land area available for recreation. For example, reach E-1E has the highest estimated radionuclide dose (44 mrem/yr for the trail user scenario), but it is one of the shortest, narrowest, and roughest reaches in the Mortandad watershed and has no developed trails or other features that attract trail users. Reach E-1E is also in a part of the Laboratory with access controls and access requirements and has signs that discourage the specific recreational activity being assessed. In addition, the estimated dose of 44 mrem/yr is below the 100 mrem/yr dose limit established by DOE for

radiation workers, indicating that trained workers conducting environmental or other work in this area would not be expected to exceed dose limits for these specific and occasional activities. As a further point of comparison, dose to the trail user would be less than 15 mrem/yr if 50 h/yr was spent in reach E-1E (instead of the 200 h//yr assumed for the trail user).

For both carcinogens and radionuclides, the exposure assessment should be evaluating incremental exposures that are greater than background. Representative concentrations are calculated that include background concentrations. For the most part, background exposures are likely negligible with the exception of some metals in sediment and surface water (e.g., arsenic) and do not lead to overestimating risk or dose.

Dermal contact with sediments and incidental soil ingestion exposure pathways each have a second exposure characteristic in addition to time spent on-site that was biased in a protective manner. The soil adherence factors that were used to define soil loading on skin for children and adults are both protectively biased. The adult adherence factor is based on a high-exposure activity (gardening) that probably would result in greater exposure than would be the case during trail use. Adult soil ingestion was assumed to be 100 mg/d, which is twice the EPA-recommended value for adults (EPA 1997, 66596).

Radionuclides in reach E-1E represent the greatest potential for risk for adult trail users, and the largest fraction of dose is related to external gamma radiation from cesium-137. Because external gamma radiation is the main contributor to radionuclide dose, the assessment should also be protective of child exposures because behaviors that increase child exposure through some pathways (incidental soil ingestion and dermal contact) play basically no role in external gamma dose.

Exposure related to external irradiation from soil is primarily a function of time spent on-site. However, the external DCFs used in the calculation of external dose protectively assume an effectively infinite area and depth of contamination. The contaminated sediments in reach E-1E, where external irradiation was an important contributor to trail user dose, are approximately 200 m long and average 3 m in width and less than 1 m in depth. The calculated dose through external irradiation from cesium-137, assuming an infinite source, would likely be twice as large as would actually be the case given the described source geometry of reach E-1E. Actual external irradiation received during recreational activities would probably be lower, assuming that receptors are not consistently in the center of the contaminated area.

An important aspect of uncertainty in exposure to COPCs in surface water relates to exposure intensity. Dermal contact and surface water ingestion were assumed to occur 20 times per year for 30 years (trail user). There is no empirical basis for this assumption, which was developed to bound a high-end exposure condition. Potential contact by adults with surface water in the Mortandad watershed would be highly intermittent at some locations based on the limited availability of water. It is also unlikely that a Laboratory employee would be drinking surface water, which is in some cases nonpotable effluent.

8.2.6.3 Toxicity Assessment

The evaluation of uncertainty pertaining to the toxicity assessment focuses primarily on the toxicology of cesium-137 because this COPC was primarily responsible for the calculated radionuclide dose to be greater than 15 mrem/yr in one reach. Nearly all of the dose for cesium-137 for the trail user scenario is associated with external gamma radiation (LANL 2005, 88493, Table A-2, p. A-2). The main uncertainties associated with the external radiation DCF relate to the geometry of the source and the receptor. Uncertainties associated with the source term were discussed in Section 8.2.6.2.

Table 8.2-10 provides a summary of the COPCs where the reference dose or SF values differ between various sources used in this assessment. The toxicity values used by NMED or EPA Region 6 are

basically the same, but these values differ from the sources used in Laboratory guidance or reports. For barium, copper, and manganese, the Laboratory toxicity values were more protective. There are three cases where the values used by NMED are more protective and the impact on the assessment for these analytes is considered.

- *Aroclor-1254*: The inhalation cancer risk slope factor used by NMED is 6 times more protective than the Laboratory value. However, the inhalation pathway is orders of magnitude less important than soil ingestion from an exposure perspective, so this difference in the inhalation cancer slope would not change the estimated risks from Aroclor-1254.
- *Thallium*: The oral reference dose used by NMED is about 20% lower (more protective) than the Laboratory value. This level of difference in thallium toxicity would not change any of the noncarcinogen assessments because the largest ratio for thallium was 0.003.
- *Vanadium*: The oral reference dose used by NMED is 7 times lower (more protective) than the Laboratory value. This level of difference in vanadium toxicity would not change any of the noncarcinogen assessments because the largest ratio for vanadium was 0.004.

8.2.7 Summary of the Human Health Risk Assessment

The health effects associated with COPCs in the Mortandad watershed were assessed relative to a radiological dose criterion of 15 mrem/yr for sediment and 4 mrem/yr for water, a chemical cancer risk criterion of 1×10^{-5}, and a chemical hazard criterion of 1.0. The risk assessment results are below these thresholds for the trail user with one exception. The calculated radionuclide dose for reach E-1E was 44 mrem/yr, and this was almost entirely related to sediment COPCs and primarily related to external gamma radiation from cesium-137.

The sediment radionuclide dose corresponds to a radiological risk of approximately 2×10^{-4} based on risk-based recreational radionuclide SALs. Radiological risks from surface water in reach E-1E will be negligible as sediment contributed about 99.4% of the dose. Radiological risks from sediments for reaches M-2W, M-2E, and M-3 were 2×10^{-5} to 3×10^{-5}, and radiological risks in other reaches ranged from 2×10^{-8} to 9×10^{-6}.

The nonsuitability of E-1E for traditional trail use and access restrictions in this part of the Laboratory, combined with conservatism included in the risk assessment, indicates that it is unlikely that actual recreational users of the Mortandad watershed would receive a dose exceeding 15 mrem/yr. Surface water risk results are below all adverse effect levels.

9.0 CONCLUSIONS AND RECOMMENDATIONS

Investigations of sediment, surface water, and groundwater in the Mortandad watershed indicate that inorganic, organic, and radionuclide COPCs are present in these media at concentrations above screening levels and federal and/or state groundwater standards. These COPCs are derived from several sources, including Laboratory SWMUs and AOCs, runoff from developed areas, and natural sources such as noncontaminated soils, sediments, and bedrock.

The spatial distribution of contaminants in the Mortandad watershed, supported by effluent discharge data, indicates that the TA-50 RLWTF outfall into Effluent Canyon, which has been active since 1963, is the most important source of contamination with respect to potential human health risk and groundwater impacts. Source areas for Laboratory-derived COPECs that are most important in the assessment of potential ecological risk include TA-48 outfalls into the head of Effluent Canyon and into Mortandad

Canyon, the TA-50 RLWTF outfall, and additional releases from TA-50 or TA-35 into the head of Ten Site Canyon. The impacts of additional Laboratory sources (e.g., outfalls from the former TA-35 WWTP, wastewater lagoons, and filter beds) are indicated by the characterization data, although the concentrations, extent, and inventory of COPCs from these sources are generally minor compared with the sources listed above.

Contaminants in sediment that were originally released from the TA-50 RLWTF outfall are largely or entirely restricted to approximately 4 km (2.5 mi) of canyon bottom downcanyon from the outfall. The COPCs in alluvial groundwater derived from the RLWTF outfall are also restricted to this area. The infiltration of stormwater into alluvium, particularly upcanyon from the Mortandad–Ten Site Canyon confluence, results in a complete loss of surface water in most runoff events and deposition of contaminated sediment. The most important sediment deposition area is in the 0.6 km (0.4 mi) of canyon bottom west of the confluence (reach M-3E), and approximately 50% of the inventory of most radionuclides in sediments occurs there. No floods have been recorded crossing the Laboratory-San Ildefonso Pueblo boundary since RLWTF discharges began in 1963, and only one event before 1963 is recorded as having reached the Laboratory boundary in August 1952. Construction of the current sediment traps in Mortandad Canyon east of the Ten Site Canyon confluence in 1986 enhanced a process of infiltration and sediment deposition that was occurring previously.

Contaminant concentrations in sediment, surface water, and alluvial groundwater in the Mortandad watershed have generally decreased over time, indicating that the initial SWMU and AOC sources are no longer major contributors to contamination in canyons media. The canyon bottom sediment deposits contain the largest inventory of adsorbed contaminants that are susceptible to remobilization and transport in floods and are now the primary source for ongoing surface water and alluvial groundwater contamination. Therefore, any future efforts that may be required to address contaminants in canyons media should address the current distribution of contaminants in sediment and associated groundwater rather than in the original source areas.

In contrast, contaminant concentrations in deeper perched-intermediate or regional groundwater have increased over time, indicating the migration of mobile constituents through the vadose zone and into deeper zones of saturation. Vadose-zone pore-water concentration profiles indicate that these mobile contaminants have percolated in the subsurface. Currently, the majority of the mass of the nonsorbing contaminants—nitrate, perchlorate, and tritium—is located within the vadose zone, particularly beneath the area near and east of the confluence of Mortandad and Ten Site Canyons. Chromium is present in the regional aquifer in one characterization well (R-28) above groundwater standards; chromium, nitrate, perchlorate, and tritium have been measured above groundwater standards in perched intermediate-depth groundwater in one or more wells. Iron and manganese have also been measured above drinking water standards in regional groundwater in one well (R-14) and nickel in another well (R-33), although available data indicate that these results represent naturally occurring constituents and not Laboratory-derived contamination. Additional evaluations will be necessary to further understand contamination in intermediate-depth and regional groundwater and to consider potential remedial actions. A more detailed evaluation of chromium contamination in groundwater is currently in progress (LANL 2006, 91987) and will be available in an interim measures report scheduled for completion in November 2006.

Many organic, inorganic, and radionuclide COPECs have been identified in the ecological screening assessments; subsequently, a plan for a base line ecological risk assessment was developed. This process is based upon the eight-step EPA ecological risk assessment guidance for Superfund (EPA 1997, 59370). The base line ecological risk assessment evaluated evidence of ecological risks from COPECs to omnivorous mammals, insect-eating birds, plants, earthworms, aquatic invertebrates, algae, and two T&E species: the Mexican spotted owl and the southwestern willow flycatcher. The multiple lines

of evidence did not identify adverse effects to terrestrial or aquatic receptors that currently inhabit the watershed. Therefore, no mitigation is necessary.

The site-specific human health risk assessment uses a trail user exposure scenario to represent the present-day and reasonably foreseeable future land use in canyons throughout the Mortandad watershed. The assessment results indicate that for the trail user scenario, no areas in the Mortandad watershed have contaminant concentrations greater than levels acceptable for noncarcinogens (HI of 1) or carcinogens (incremental cancer risk criterion of 1×10^{-5}) in sediment or water. However, the radionuclide dose for one area, reach E-1E in Effluent Canyon downcanyon from the TA-50 RLWTF outfall, exceeds the target dose limit of 15 mrem/yr. The calculated dose for reach E-1E, 52 mrem/yr (corresponding to a radiological risk of approximately 2×10^{-4}), is primarily related to external gamma radiation from cesium-137 in sediment. The radionuclide dose limit of 4 mrem/yr in water was not exceeded at any location.

As discussed in Section 8.2.6, reach E-1E is a short, steep, and rocky area that has no developed trail within the contaminated area, and it is unlikely that recreational users of the Mortandad watershed use this reach as much as assumed in the trail user scenario (1 h/d and 200 d/yr). Other protectively biased assumptions are incorporated into the exposure assessment, also contributing to an overestimate of potential dose. In addition, the area is currently posted as a "soil contamination area," and posting also states that "access is restricted to workers on official business," further discouraging recreational use in reach E-1E. Therefore, no remedial action is proposed to reduce the potential radiation dose to recreational users of Effluent Canyon, although it is recommended that appropriate posting be maintained.

Evaluations of the changes in COPC concentrations over time for sediment, surface water, and alluvial groundwater indicate that concentrations are either relatively stable or are decreasing for contaminants derived from Laboratory SWMUs or AOCs. These decreases are associated with processes that remobilize, transport, and dilute sediment- and waterborne constituents. Radioactive decay also contributes to decreasing concentrations for some radionuclides (e.g., cesium-137, strontium-90, and tritium). Therefore, the potential for impacts to human health or ecosystems from Laboratory-derived contaminants in these media is expected to continue to decrease in the absence of new sources.

Potential future changes in the vadose-zone contamination and concentrations of contaminants in perched-intermediate and regional groundwater are less well constrained, and a corrective measures evaluation (CME) is necessary to assess the need for remedial actions. The CME will assess the fate of the contaminant mass in the vadose zone and impacts to the regional groundwater where water-supply wells are located. A more detailed evaluation of chromium contamination in groundwater is currently in progress and will be addressed in pending reports to the NMED. Monitoring in the Mortandad watershed will continue through the proposed CME process and is described in the Interim Facility-Wide Groundwater Monitoring Plan.

In summary, the results of this investigation indicate that human health risks are acceptable for present-day and foreseeable future land uses, assuming that recreational use of Effluent Canyon below the TA-50 RLWTF outfall continues to be discouraged. In addition, no adverse ecological effects were observed within terrestrial and aquatic systems in the Mortandad watershed. Therefore, corrective actions are not needed to mitigate unacceptable risks. However, a CME is proposed to address contamination in groundwater.

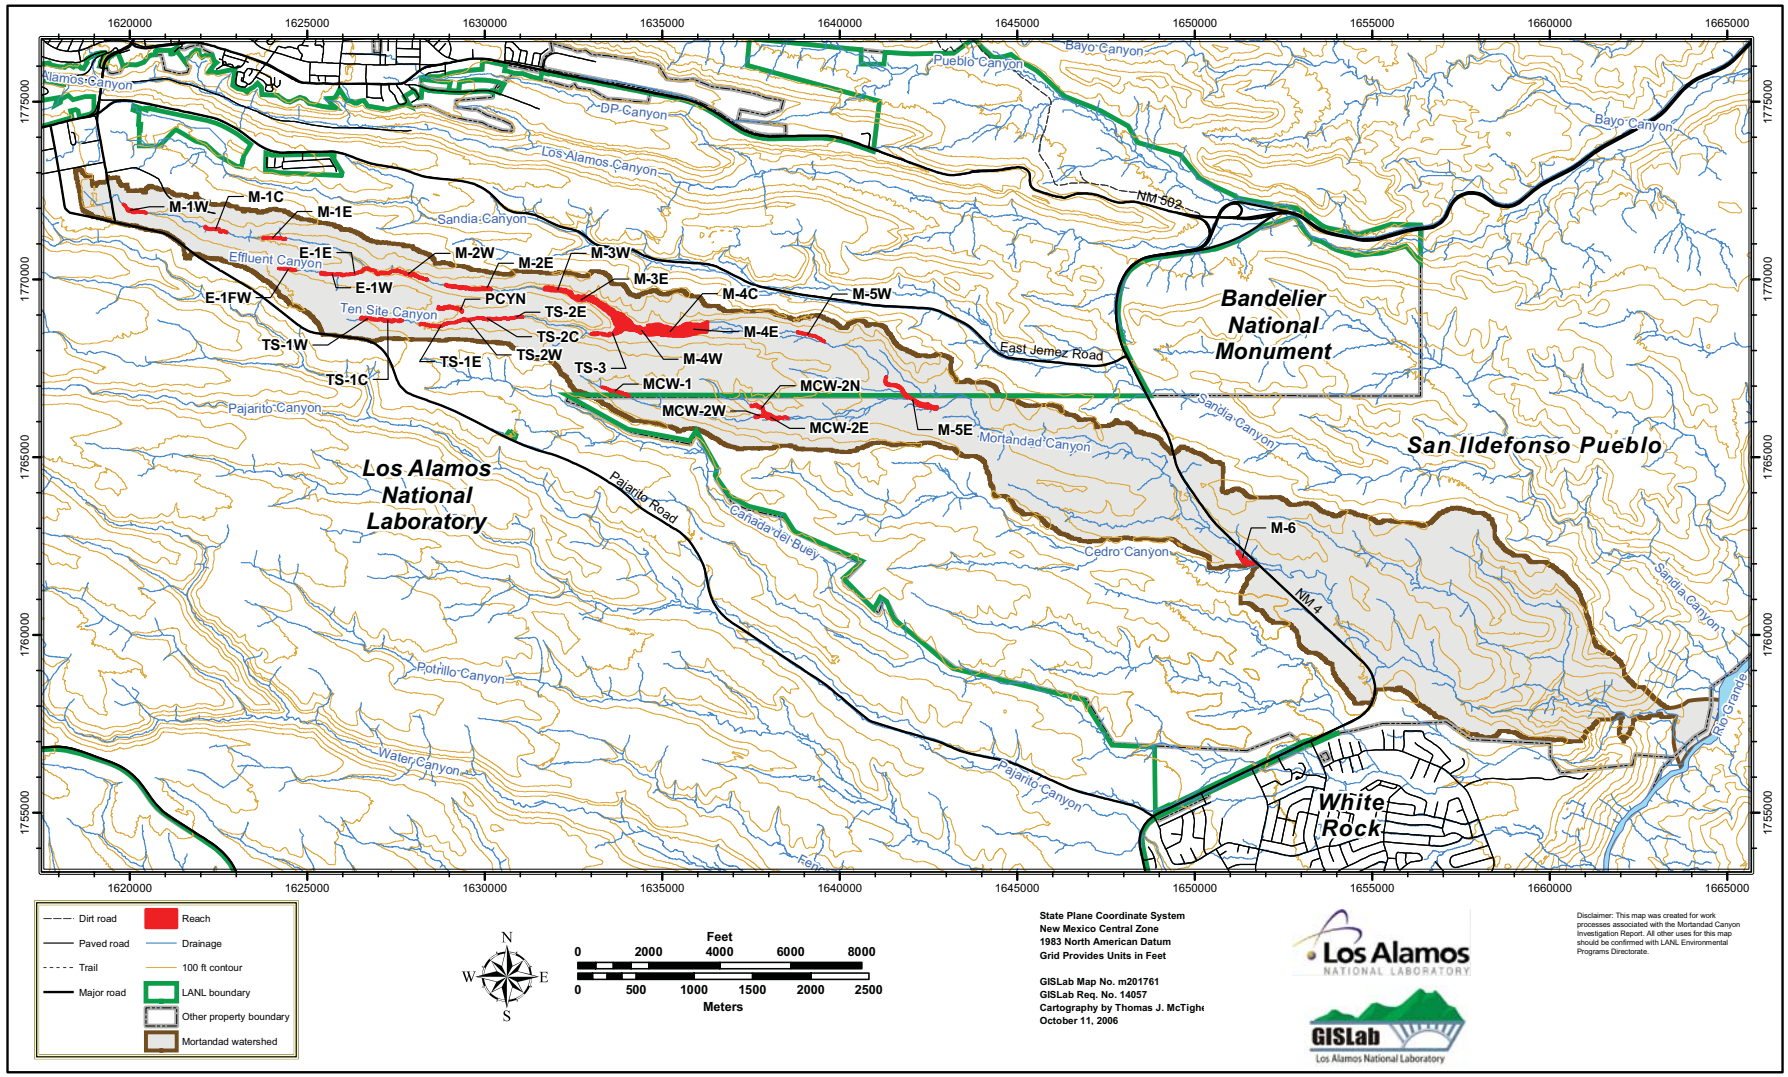

Figure 3.1-1. Reaches in the Mortandad watershed

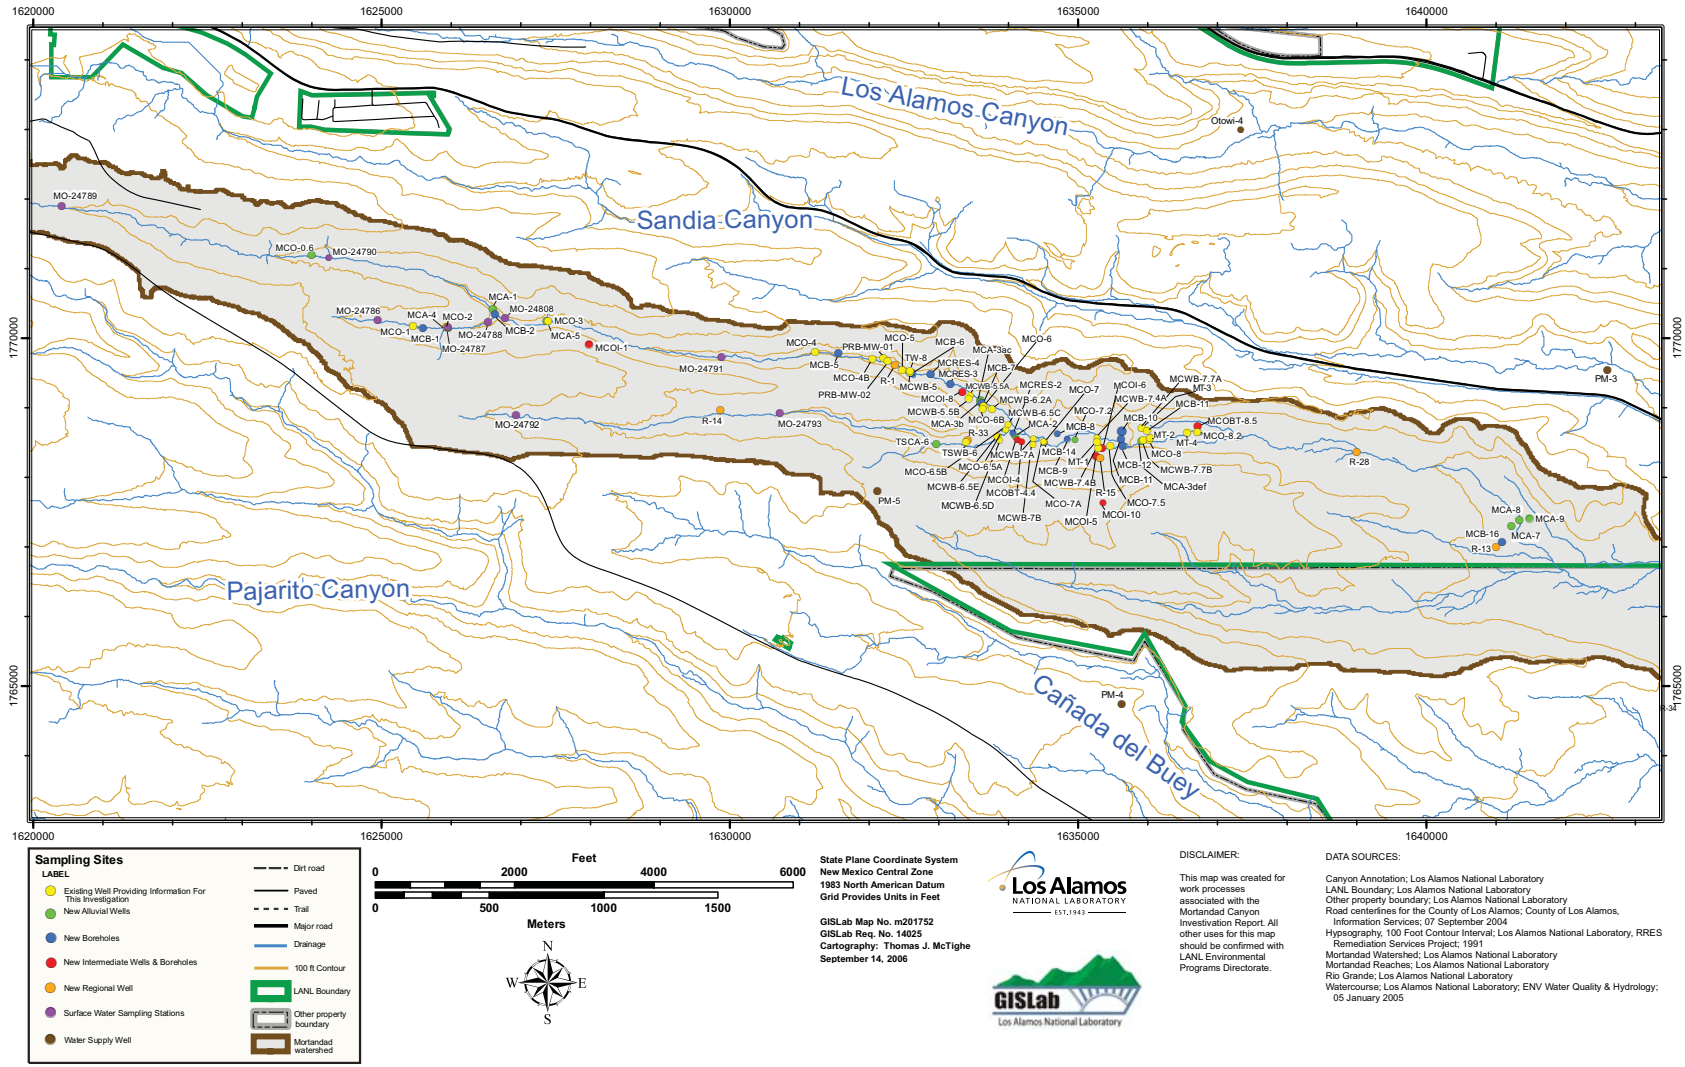

Figure 3.2-1. Water-sampling locations in the Mortandad watershed

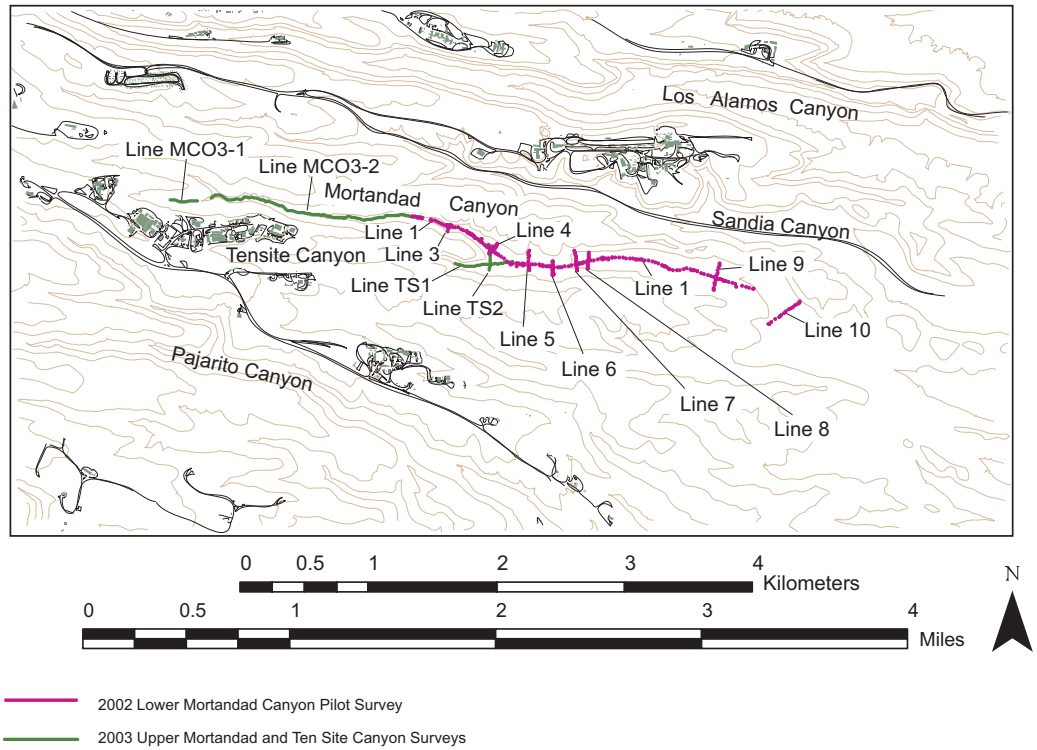

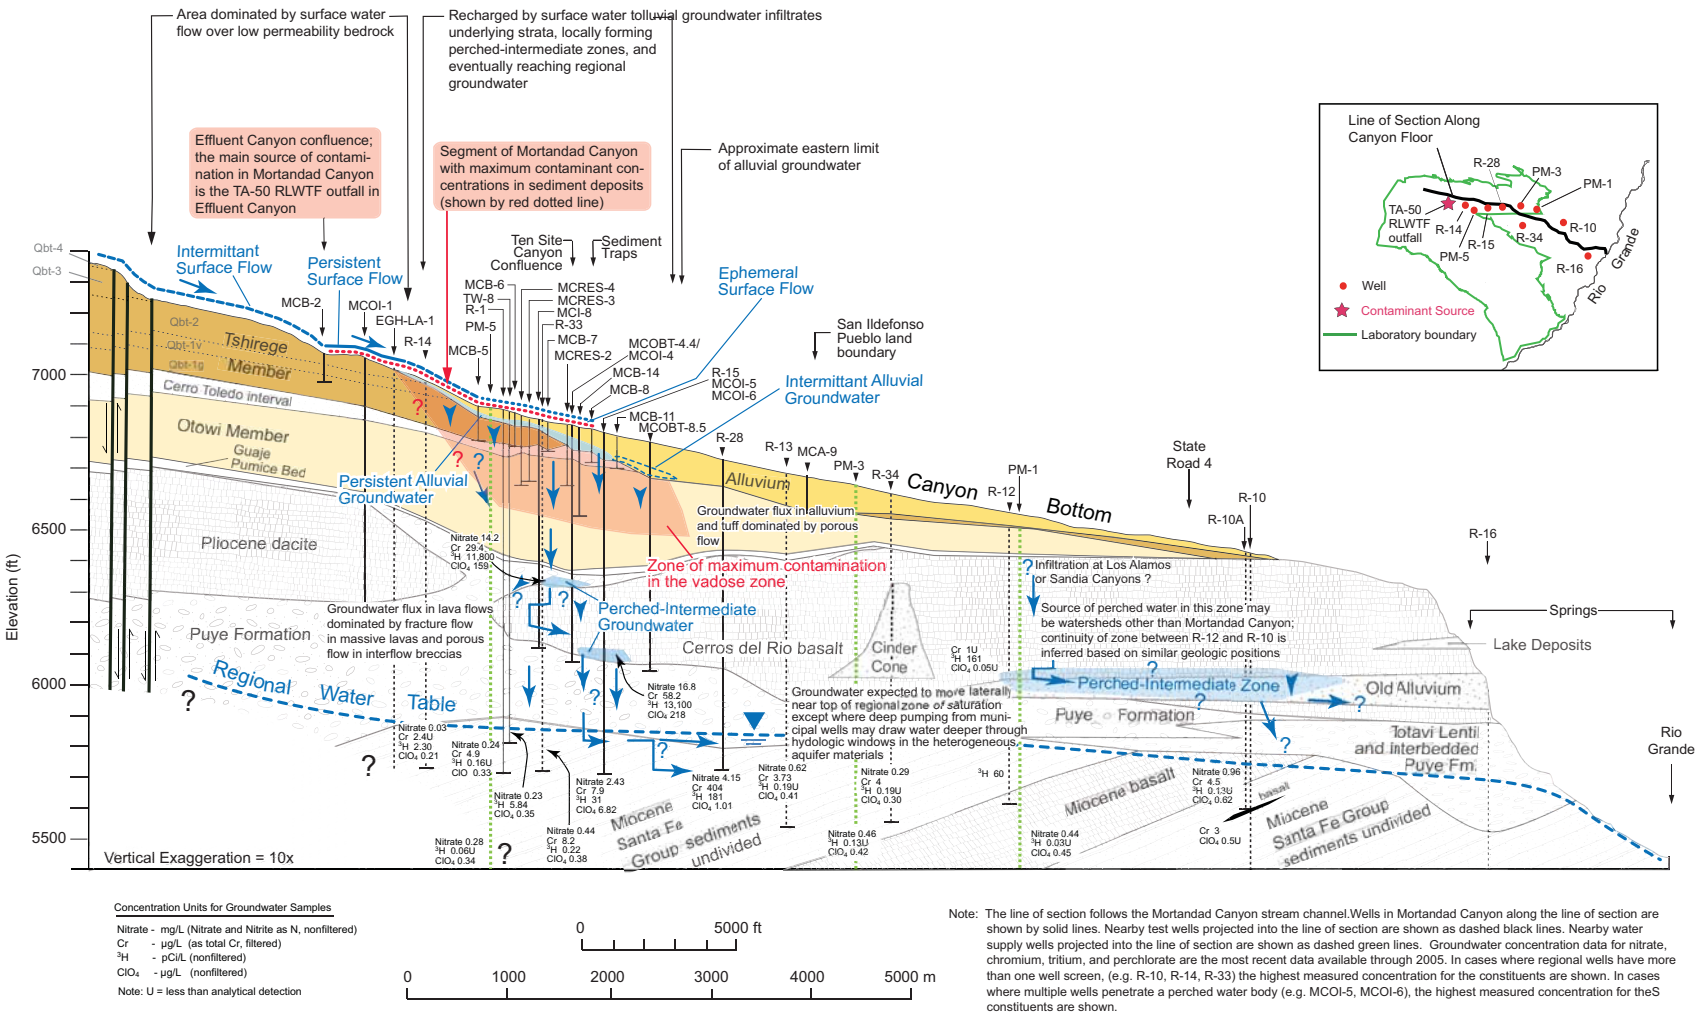

Figure 4.2-1. Locations of Surface-Based Direct-Current Resistivity Lines Collected by Geophex, Inc. in Mortandad Canyon

Note: The line of section follows the Mortandad Canyon stream channel.Wells in Mortandad Canyon along the line of section are shown by solid lines. Nearby test wells projected into the line of section are shown as dashed black lines. Nearby water supply wells projected into the line of section are shown as dashed green lines. Groundwater concentration data for nitrate, chromium, tritium, and perchlorate are the most recent data available through 2005. In cases where regional wells have more than one well screen, (e.g. R-10, R-14, R-33) the highest measured concentration for the constituents are shown. In cases where multiple wells penetrate a perched water body (e.g. MCOI-5, MCOI-6), the highest measured concentration for theS constituents are shown.

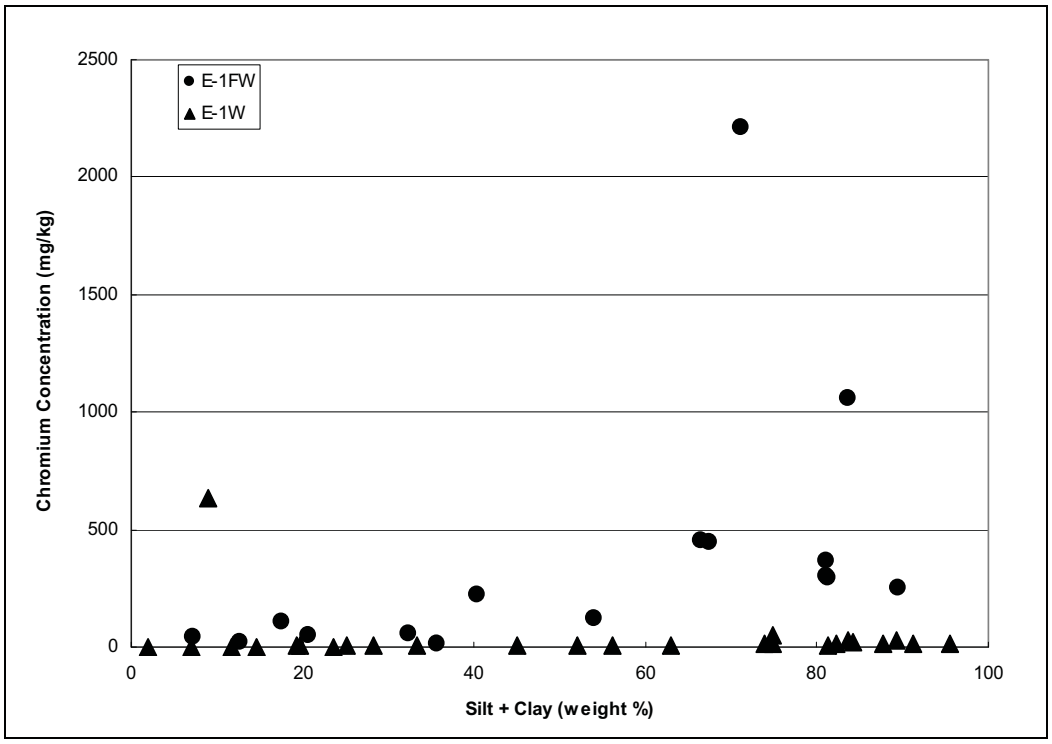

Figure 7.1-22. Scatter plot showing relations between chromium concentration and silt and clay content in reaches E-1FW and E-1W

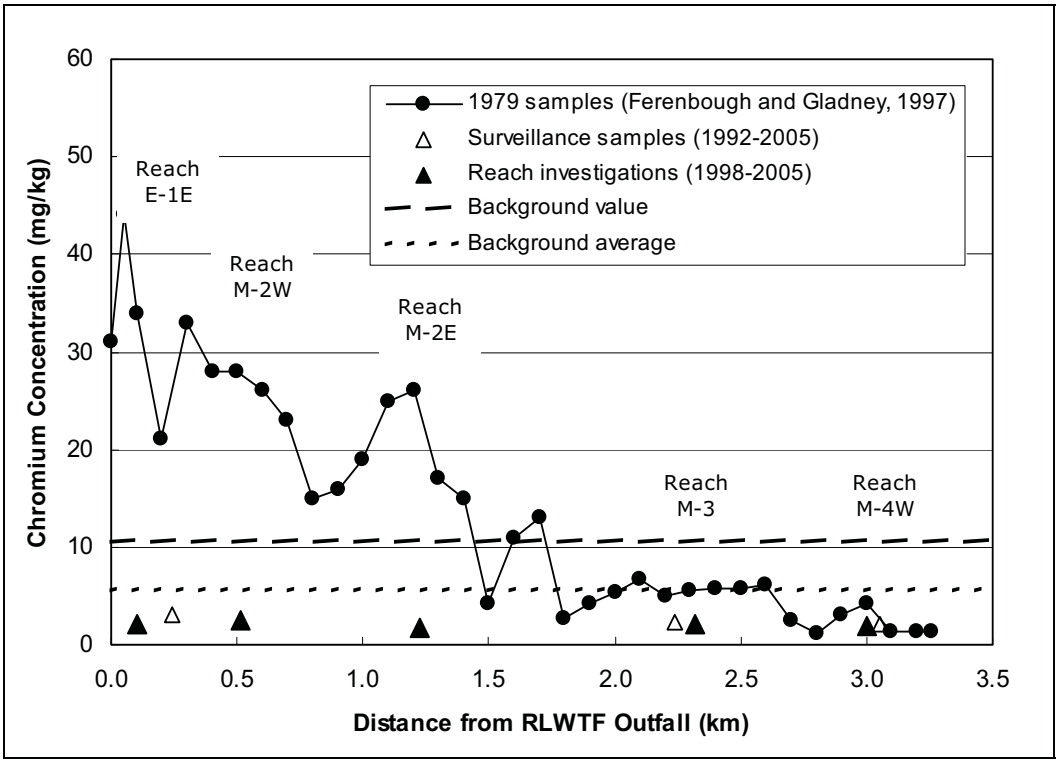

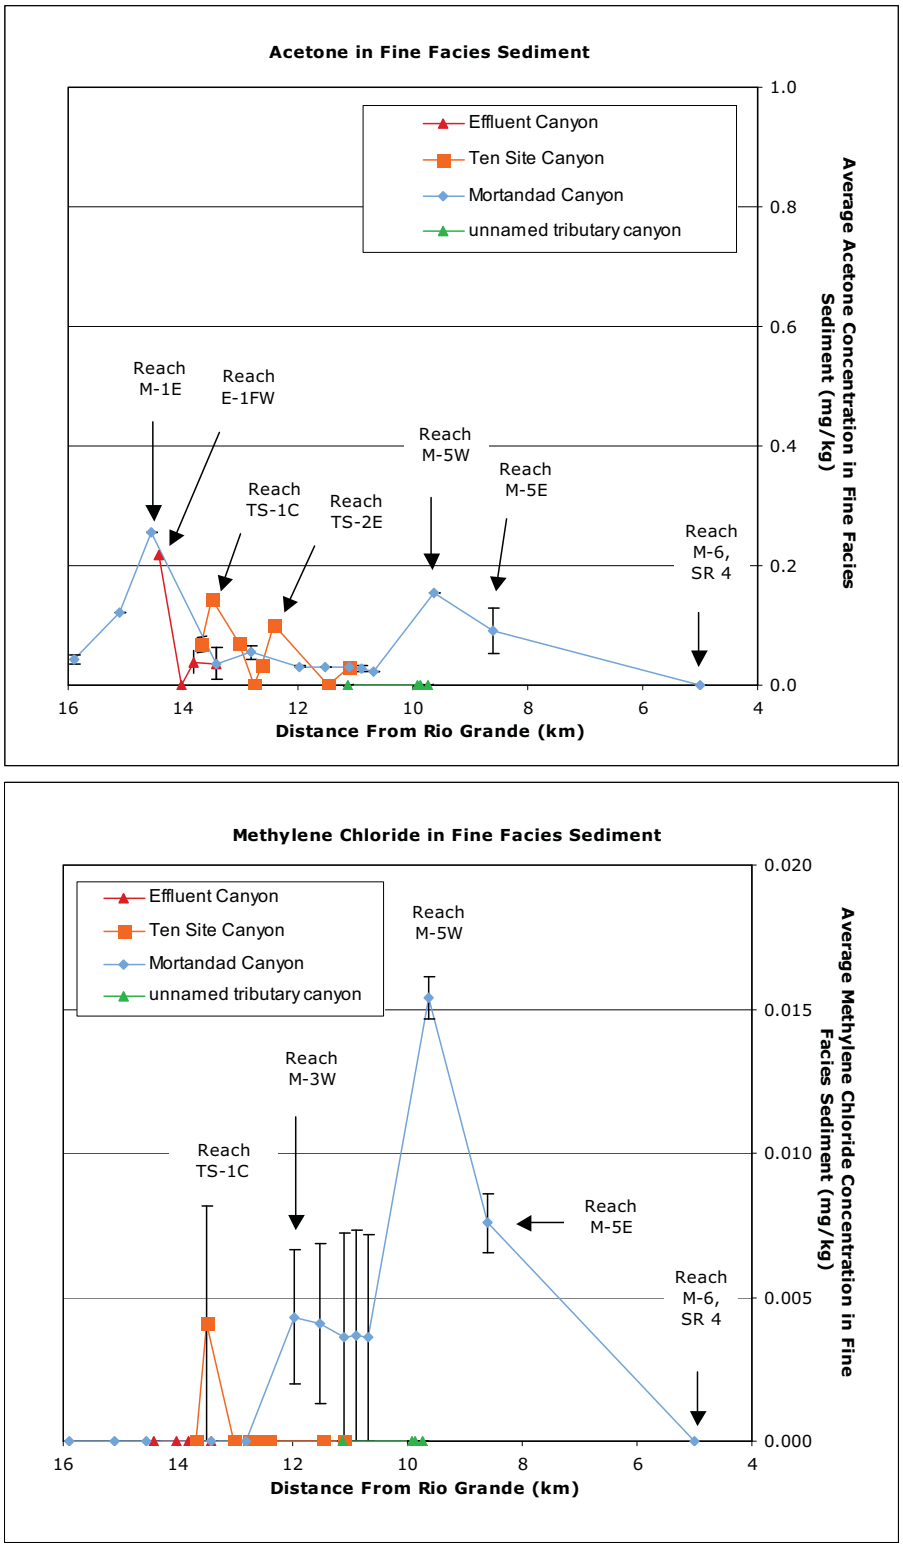

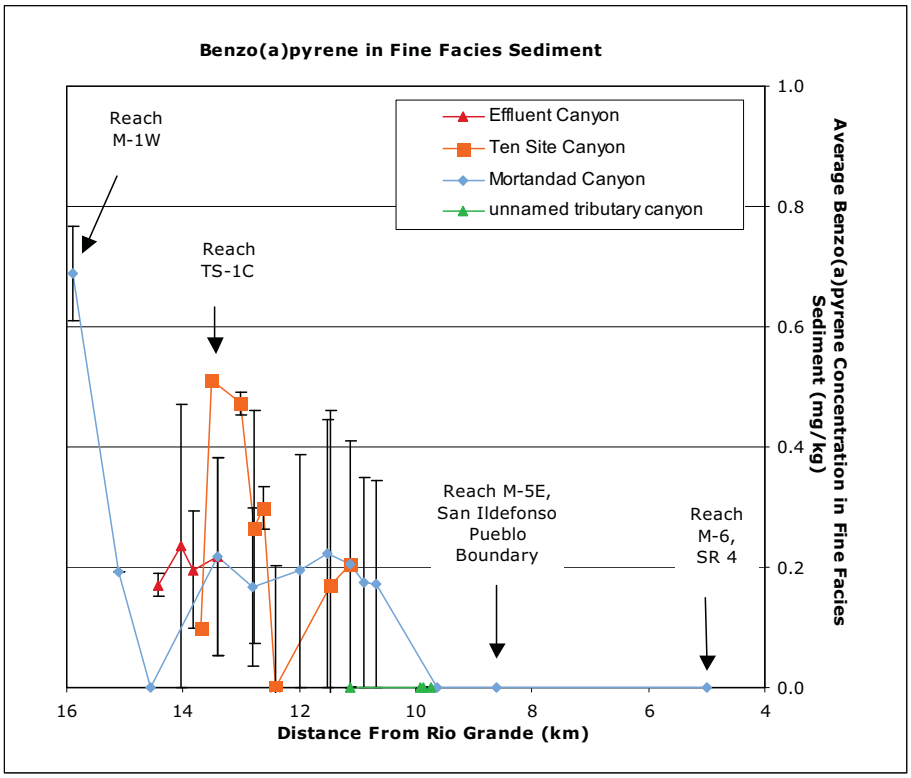

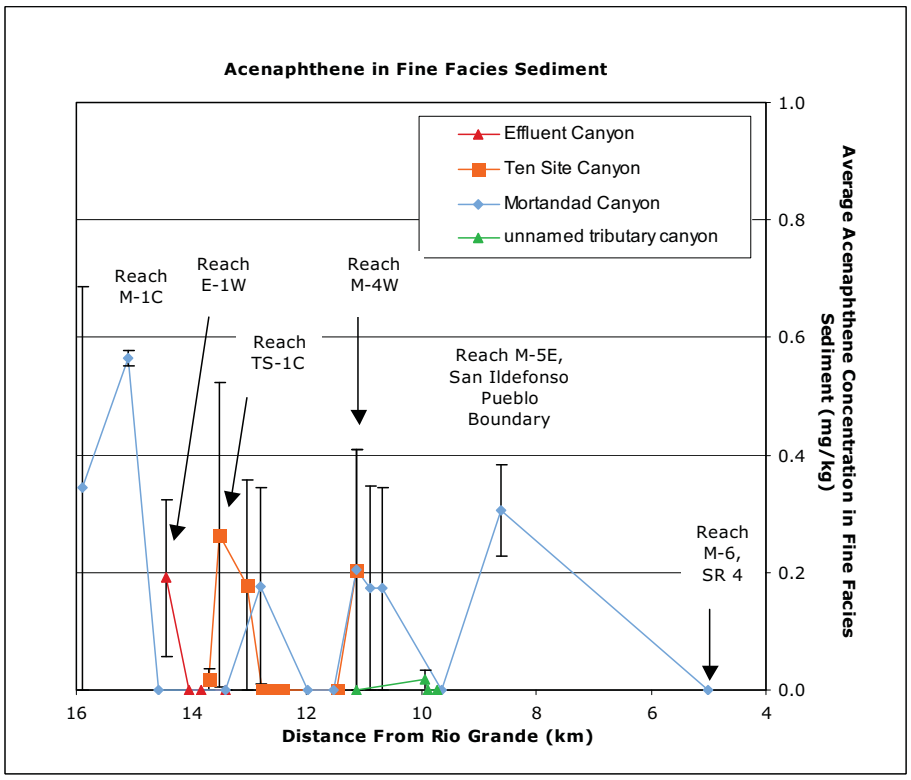

Figure 7.1-23. Chromium concentrations from active channel samples collected in 1979 (Ferenbaugh and Gladney 1997, 93715) and from later investigations plotted versus distance from TA-50 RLWTF outfall

Notes: Error bars indicate upper and lower bounds based on replacing nondetect values with either the detection limit or zero. A value of zero is shown where there are no detected results.

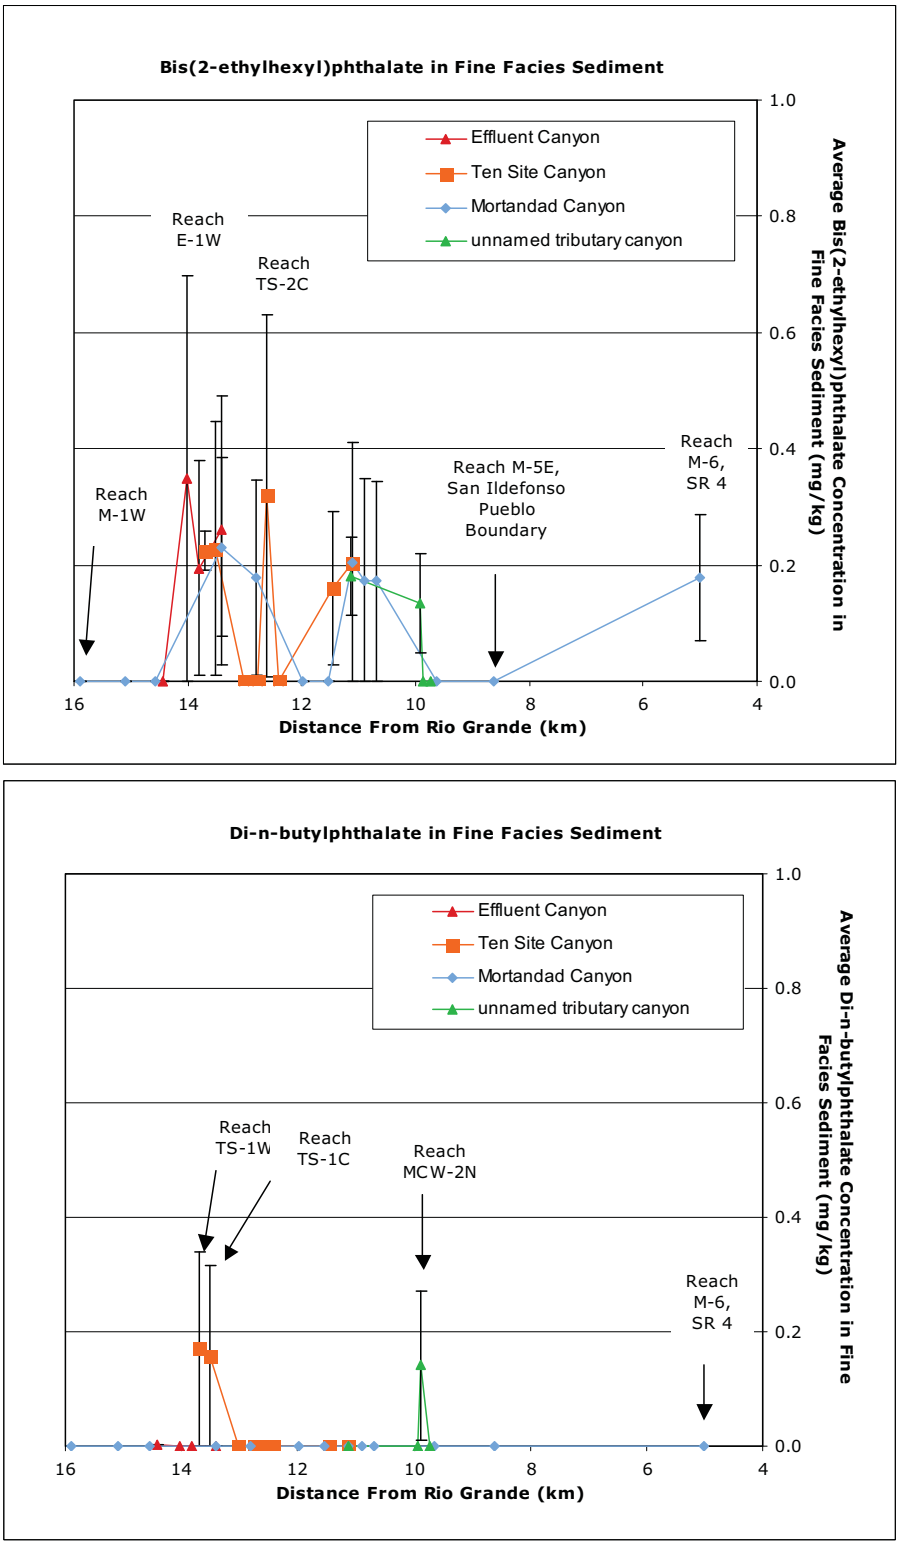

Figure 7.1-24. Estimated average concentrations of the PCBs Aroclor-1260 and Aroclor-1254 in fine facies sediment in the Mortandad watershed

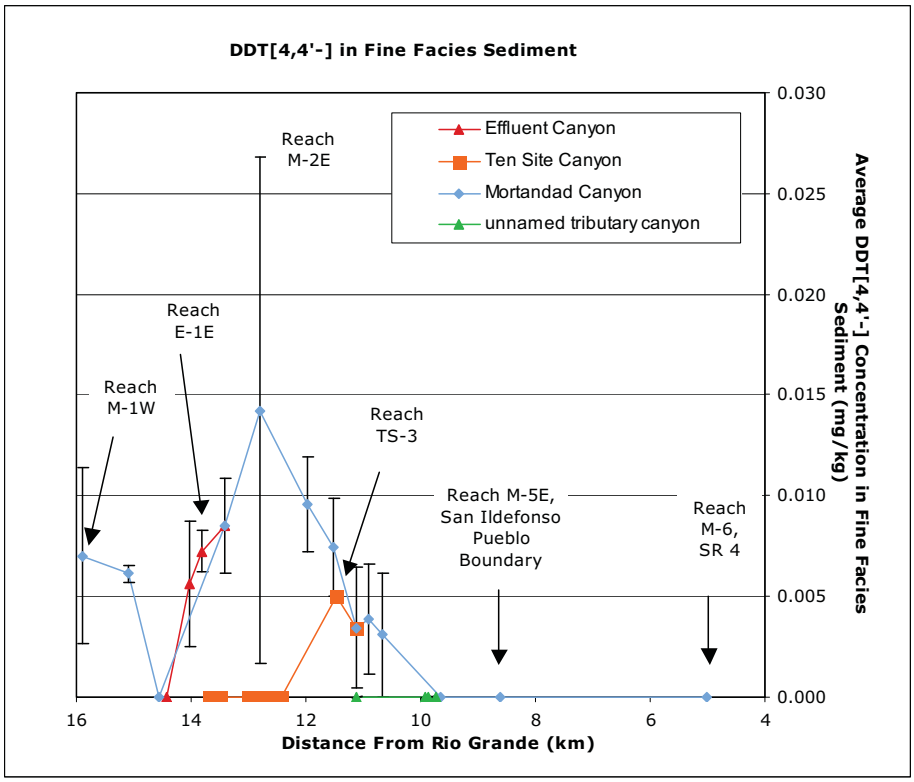

Notes: Error bars indicate upper and lower bounds based on replacing nondetect values with either the detection limit or zero. A value of zero is shown where there are no detected results.

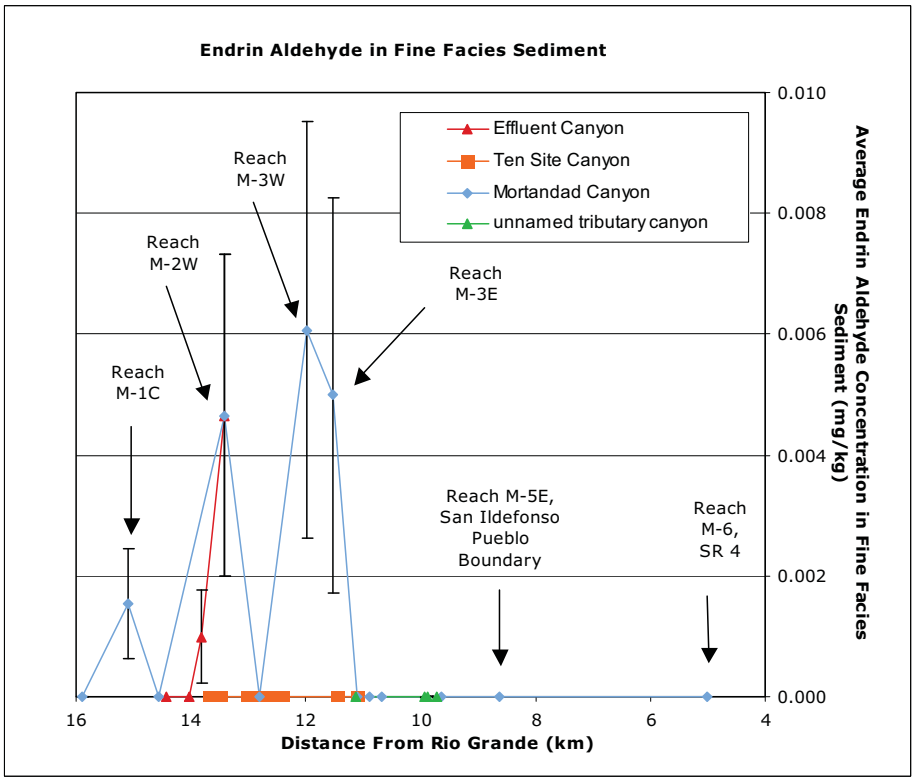

Figure 7.1-25. Estimated average concentrations of the PAHs benzo(a)pyrene and acenaphthene in fine facies sediment in the Mortandad watershed

Notes: Error bars indicate upper and lower bounds based on replacing nondetect values with either the detection limit or zero. A value of zero is shown where there are no detected results.

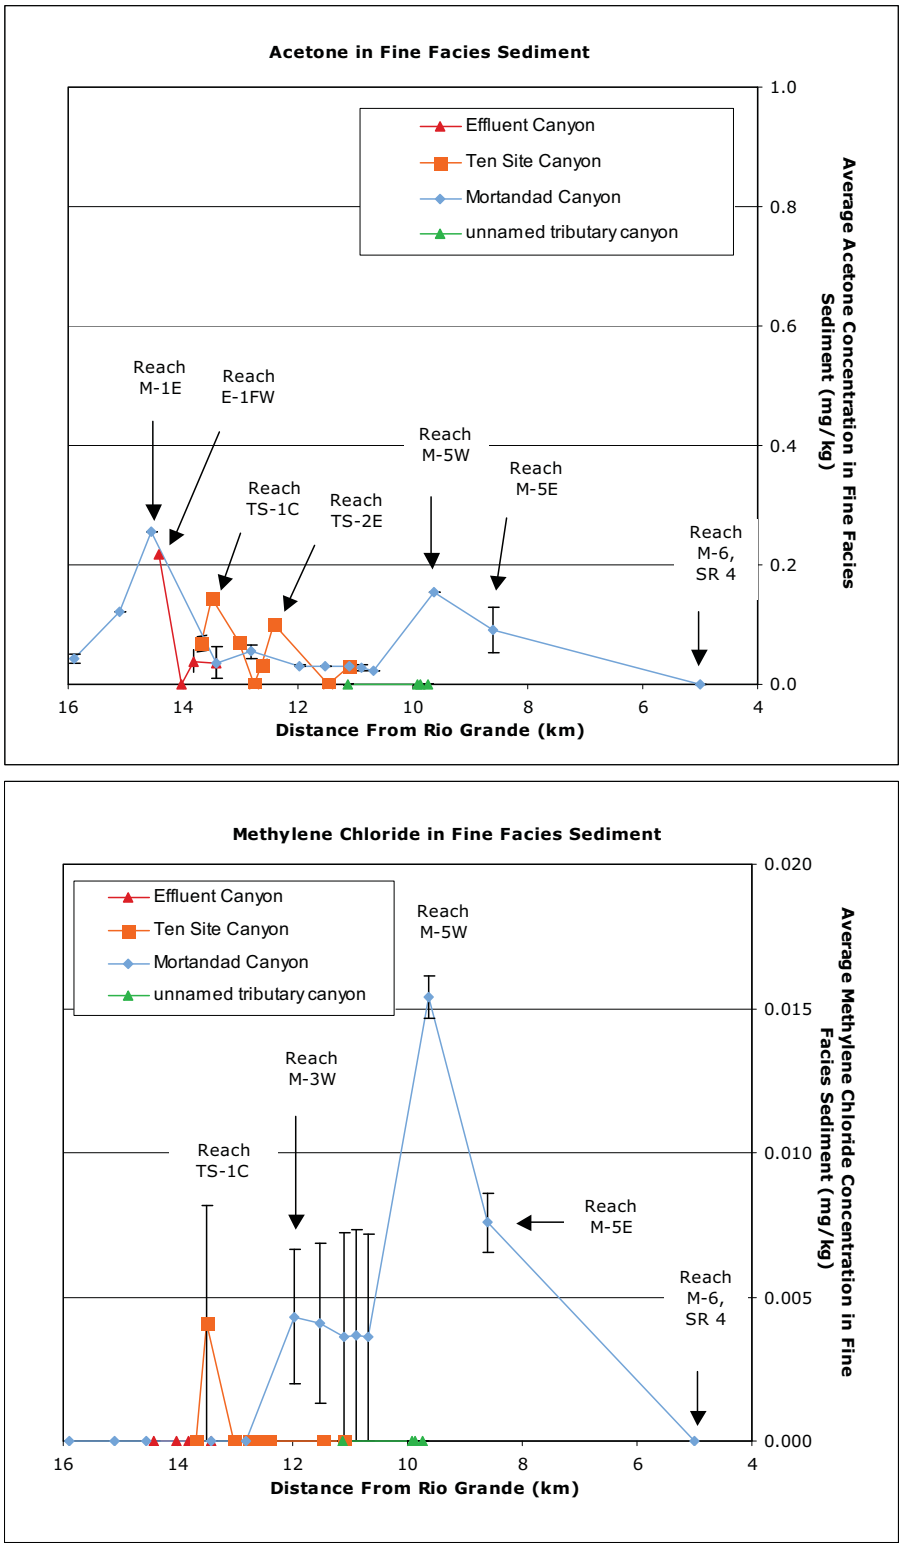

Figure 7.1-26. Estimated average concentrations of the SVOCs bis(2-ethylhexyl)phthalate and di-n-butylphthalate in fine facies sediment in the Mortandad watershed

Notes: Error bars indicate upper and lower bounds based on replacing nondetect values with either the detection limit or zero. A value of zero is shown where there are no detected results.

Figure 7.1-27. Estimated average concentrations of the pesticides DDT and endrin aldehyde in fine facies sediment in the Mortandad watershed

Notes: Error bars indicate upper and lower bounds based on replacing nondetect values with either the detection limit or zero. A value of zero is shown where there are no detected results.

Figure 7.1-28. Estimated average concentrations of the VOCs acetone and methylene chloride in fine facies sediment in the Mortandad watershed

	TS-3	TS-3	11.46	0.31	2001, 2005	Upcanyon of Mortandad Canyon
Unnamed tributary canyon	MCW-1	MCW-1	11.13	0.25	2003, 2005	Upper part of unnamed tributary below TA-5
	MCW-2 North	MCW-2N	9.93	0.20	2003, 2005	Tributary below Far Point firing site (SWMU 05-001[c])
	MCW-2 West	MCW-2W	9.88	0.10	2003, 2005	Upcanyon of Far Point firing site tributary
	MCW-2 East	MCW-2E	9.73	0.20	2003, 2005	Downcanyon of Far Point firing site tributary

[a] In Section 6 and Appendix C tables, these 2 reaches are combined and reported as "M-3."

[b] In Section 6 and Appendix C tables, these 3 reaches are combined and reported as "M-4."

Table 3.2-1
Mortandad Canyon Surface and Groundwater Sampling Locations and Rationale

Location Name	Location and Rationale
Alluvial Groundwater Wells (West to East)	
MCO-0.6	Mortandad Canyon north of TA-48. Westernmost alluvial groundwater monitoring point in Mortandad Canyon. Provides samples of base line alluvial water upstream of the Mortandad and Effluent Canyons confluence and downstream of all potential contaminant sources in upper Mortandad Canyon.
MCA-1	Mortandad Canyon above confluence with Effluent Canyon. New well that provides samples of alluvial groundwater from the upper part of the Mortandad Canyon watershed above the influence of the TA-50 RLWTF outfall (NPDES outfall EPA03A-051).
MCA-4	Effluent Canyon. New well located downcanyon of release sites in Effluent Canyon and upcanyon of TA-50 RLWTF outfall. Provides continuity with historical groundwater quality data. Replacement for well MCO-2.
MCO-2	Effluent Canyon. Location is downcanyon of release sites in Effluent Canyon and upcanyon of TA-50 RLWTF outfall. Sampled when insufficient water was obtained from MCA-4.
MCA-5	Mortandad Canyon below confluence with Effluent Canyon. New well that provides samples of alluvial groundwater representing contributions from both Effluent Canyon and the upper part of the Mortandad Canyon watershed. First groundwater monitoring point below the TA-50 RLWTF outfall. Provides continuity with historical groundwater quality data. Replacement for well MCO-3.
MCO-4B	Mortandad Canyon near the east end of the narrow, deeply incised portion of the canyon. Provides samples of alluvial water upcanyon of the permeable reactive barrier and the major zone of infiltration where the canyon widens to the east. Provides continuity with historical groundwater quality data.
MCO-5	Mortandad Canyon near TW-8. Provides samples of alluvial water where the canyon widens eastward and alluvium thickens. First groundwater monitoring point downcanyon of the permeable reactive barrier. Provides continuity with historical groundwater quality data.
MCO-6	Mortandad Canyon above confluence with Ten Site Canyon. Location provides samples of alluvial groundwater from the upper part of the Mortandad Canyon watershed above the influence of release sites in the Ten Site Canyon watershed. Provides continuity with historical groundwater quality data.
MCA-2	Confluence of Mortandad and Ten Site canyons. New well that provides samples of alluvial groundwater that may a source of intermediate-perched groundwater encountered at MCI-4 and MCOBT-4.4. Equivalent to well MCO-6.8 in the “Work Plan for Mortandad Canyon” (LANL 1997, 56835).
MCO-7	Mortandad Canyon below confluence with Ten Site Canyon. Location provides samples of alluvial groundwater representing contributions from both Ten Site Canyon and the upper and middle parts of the Mortandad Canyon watershed. Located west of sediment traps. Provides continuity with historical groundwater quality data.
TSCA-6	Ten Site Canyon. New well located downcanyon of historic release sites at TA-35. Formerly called MCA-6. The TSCA-6 alluvial well was installed in the MCB-15 core hole after backfilling the deep borehole to the level of alluvial saturation.
MCO-7.2	Mortandad Canyon east of sediment traps. New well installed to determine if suballuvium groundwater occurs within Cerro Toledo deposits in this part of Mortandad Canyon. This well is dry although alluvial groundwater was present in overlying alluvium during drilling.

Table 3.2-1 (continued)

Location Name	Location and Rationale
MT-1	Mortandad Canyon downcanyon of sediment traps. Provides continuity with historical groundwater quality data. Alternative water sampling well for alluvial groundwater near MCO-7.2.
MCO-7.5	Mortandad Canyon downcanyon of sediment traps. Located near the eastern extent of persistent alluvial groundwater saturation. Provides continuity with historical groundwater quality data.
MT-2	Mortandad Canyon in area of intermittent alluvial saturation.
MT-3	Mortandad Canyon in area of intermittent alluvial saturation.
MT-4	Mortandad Canyon in area of intermittent alluvial saturation.
MCA-7,-8,-9	Mortandad Canyon near eastern Laboratory boundary. Transect of new wells installed to determine if saturation occurs near the Laboratory boundary. MCA-7 (dry) was plugged and abandoned. Alluvial wells (dry) were installed in MCA-8 and MCA-9. Meets the requirement to install wells MC-13A and -13B in the "Work Plan for Mortandad Canyon" (LANL 1997, 56835).
Surface Water (West to East)	
Reach M-1W Surface Water (MO-24789)	Mortandad Canyon east of Diamond Drive. Provides base line information for surface water in uppermost part of Mortandad Canyon watershed.
Reach M-1E Surface Water (MO-24790)	Mortandad Canyon north of TA-48. Provides samples of surface water upstream of the Mortandad and Effluent Canyons confluence and downstream of all potential contaminant sources in upper Mortandad Canyon.
Reach E-1FW Surface Water (MO-24786)	Uppermost Effluent Canyon. Provides samples surface water downstream of outfalls on the east end of TA-48.
Reach E-1W Surface Water (MO-24787)	Middle Effluent Canyon. Provides samples surface water upstream of TA-50 RLWTF outfall (NPDES outfall EPA03A-051).
Reach E-1E Surface Water (MO-24788)	Effluent Canyon about 130 m (425 ft) downstream of the TA-50 RLWTF outfall. Provides samples of surface water downstream of all Effluent Canyon contaminant sources.
Reach M-2W Surface Water (MO-24808)	Below confluence of Mortandad and Effluent Canyons at the E200 gaging station. Provides samples combined Mortandad and Effluent Canyons surface water.
Reach M-2E Surface Water (MO-24791)	Mortandad Canyon about 970 m (3180 ft) downcanyon of the Effluent Canyon confluence. Provides samples of surface water near the terminus of surface water flow supported by the TA-50 RLWTF outfall.

Table 3.2-1 (continued)

Location Name	Location and Rationale
Reach TS-1W Surface Water (MO-24792)	Ten Site Canyon headwaters above TA-35.
Reach TS-2E Surface Water (MO-24793)	Ten Site Canyon downcanyon of TA-35 where surface water occurs in persistent bedrock pools.
Perched Intermediate Groundwater (West to East)	
MCOI-1	Bench south of Mortandad Canyon about 425 m (1400 ft) east of the confluence with Effluent Canyon. New borehole to investigate western extent of intermediate-perched groundwater. Borehole was moist but did not produce flowing water. Well installed but does not produce water.
MCOI-8	Mortandad Canyon between TW-8 and MCOBT-4.4. New well to investigate possible saturation was encountered in the lower part of Cerros del Rio basalts. Water level in well generally coincides with top of sump.
MCOI-4	Confluence of Mortandad and Ten Site canyons. New well completed in a thin zone of intermediate-perched groundwater that occurs in Puye Formation sedimentary deposits on top of Cerros del Rio basalts.
MCOBT-4.4	Confluence of Mortandad and Ten Site canyons. Well completed in 2001 within a thin zone of perched groundwater occurs in Puye Formation sedimentary deposits on top of Cerros del Rio basalt.
MCOI-5	Mortandad Canyon on the R-15 well pad on the south side of the canyon. New well completed in an intermediate perched groundwater that occurs in the lower part of Cerros del Rio basalts.
MCOI-6	Mortandad Canyon north of R-15 near the canyon axis. New well completed in an intermediate-perched groundwater occurs in the lower part of Cerros del Rio basalt.
MCOI-10	Mesa top south of Mortandad Canyon, south of well R-15. New borehole to investigate southern extent of intermediate perched groundwater in the Cerros del Rio basalt. Borehole was dry and backfilled.
MCOBT-8.5	Mortandad Canyon about 440 m (1450 ft) downcanyon of R-15; located near the stream channel. New borehole to investigate eastern extent of intermediate-perched groundwater in the Cerros del Rio basalt. Borehole was dry and backfilled.
Regional Groundwater (West to East)	
R-1	Mortandad Canyon in area transitioning from narrow slot canyon to the west and a broad open canyon to the east. Westernmost well for monitoring regional groundwater in Mortandad Canyon. Completed as a single screen well. R-1 is a replacement well for TW-8.
TW-8	Mortandad Canyon in area transitioning from narrow slot canyon to the west and a broad open canyon to the east.
R-14	Upper Ten Site Canyon. Location provides samples of regional groundwater downstream of historic release sites at TA-35. Well has two screens in the regional aquifer.
R-33	Lower Ten Site Canyon near confluence with Mortandad Canyon. Location provides samples of regional groundwater near confluence. Well has two screens in the regional aquifer.

Table 3.2-1 (continued)

Location Name	Location and Rationale
R-15	Mortandad Canyon. Location provides samples of regional groundwater in part of canyon where infiltration of contaminated alluvial water is expected to affect deep groundwater systems. Completed as a single screen well.
R-28	Mortandad Canyon. Location provides samples of regional groundwater downgradient of where infiltration of contaminated alluvial water is expected to affect deep groundwater systems. Completed as a single screen well.
R-13	Mortandad Canyon near the eastern Laboratory boundary. Location provides samples of regional groundwater moving off-site. Completed as a single screen well.
R-34	Cedro Canyon. Well installed at the request of San Ildefonso Pueblo to monitor groundwater on San Ildefonso lands downgradient of Mortandad Canyon. Completed as a single screen well.

Note: Gray shading indicates new wells required by the "Work Plan for Mortandad Canyon" (LANL 1997, 56835) and "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613).

Table 3.2-3
Characterization and RES Boreholes Installed in Mortandad Canyon

Borehole	Depth	Purpose and Location
Characterization Boreholes		
MCB-1	32 m (105 ft)	Determine distribution of contaminants in the vadose zone above the TA-50 outfall in Effluent Canyon. Borehole plugged and abandoned.
MCB-2	31.9 (104.5 ft)	Determine distribution of contaminants and moisture flux in the vadose zone below the TA-50 outfall near the Mortandad and Effluent Canyons confluence. Borehole is instrumented with water content and matric potential sensors.
MCB-3	NA	Determine distribution of contaminants in the vadose zone beneath the narrow slot portion of Mortandad Canyon between the confluence with Effluent Canyon and TW-8. Could not be drilled because there is no access to this portion of Mortandad Canyon.
MCB-4	NA	Determine distribution of contaminants in the vadose zone beneath the narrow slot portion of Mortandad Canyon between the confluence with Effluent Canyon and TW-8. Could not be drilled because there is no access to this portion of Mortandad Canyon.
MCB-5	31.7 m (104 ft)	Determine distribution of contaminants and moisture flux in the vadose zone beneath the narrow slot portion of Mortandad Canyon between the confluence with Effluent Canyon and TW-8. Borehole is about 205 m (670 ft) west of the permeable reactive barrier and represents westernmost access to slot portion of Mortandad Canyon. Borehole is instrumented with a vector probe.
MCB-6	27 m (89 ft)	Determine distribution of contaminants and moisture flux in the vadose zone in area where Mortandad Canyon begins to widen eastward. The borehole is about 140 m (460 ft) east of the permeable reactive barrier. Borehole is instrumented with a vector probe.
MCB-7	30.8 m (101 ft)	Determine distribution of contaminants and moisture flux in the vadose zone in Mortandad Canyon about 200 m (650 ft) upcanyon of the confluence with Ten Site Canyon. Borehole is instrumented with water content and matric potential sensors.
MCB-8	31.9 m (104.5 ft)	Determine distribution of contaminants and moisture flux in the vadose zone in the Mortandad Canyon sediment traps. Borehole is instrumented with water content and matric potential sensors.
MCB-9	31.2 m (102.5 ft)	Determine distribution of contaminants and moisture flux in the vadose zone adjacent to easternmost sediment trap in Mortandad Canyon. Borehole is instrumented with a vector probe.
MCB-10	31.7 m (104 ft)	Determine distribution of contaminants in the vadose zone near eastern limit of alluvial saturation in Mortandad Canyon. Northern borehole in north-south transect across canyon that includes MCB-11 and MCB-12. Borehole plugged and abandoned.
MCB-11	31.7 m (104 ft)	Determine distribution of contaminants and moisture flux in the vadose zone near eastern limit of alluvial saturation in Mortandad Canyon. Middle borehole in north-south transect across canyon that includes MCB-10 and MCB-12. Borehole is instrumented with water content and matric potential sensors.
MCB-12	31.9 m (104.5 ft)	Determine distribution of contaminants in the vadose zone near eastern limit of alluvial saturation in Mortandad Canyon. Southern borehole in north-south transect across canyon that includes MCB-10 and MCB-11. Borehole plugged and abandoned.
MCB-13	NA	Determine distribution of contaminants in the vadose zone in Mortandad Canyon east of persistent alluvial groundwater. Could not be drilled because this portion of Mortandad Canyon is a protected archeological zone.
MCB-14	86.6 m (284 ft)	Determine distribution of contaminants and moisture flux in the vadose zone adjacent to the westernmost Mortandad Canyon sediment trap. Borehole is instrumented with a vector probe.

Table 3.2-3 (continued)

Borehole	Depth	Purpose and Location
MCB-15	47.1 m (154.5 ft)	Determine distribution of contaminants in the vadose zone in lower Ten Site Canyon. Borehole was drilled to total depth and partially backfilled before installing alluvial well TSCO-6.
MCB-16	30.5 m (100 ft)	Determine distribution of contaminants and moisture flux in the vadose zone near the eastern Laboratory. The borehole was drilled about 32 m (105 ft) northeast of R-13. Borehole is instrumented with water content and matric potential sensors.
RES Boreholes		
MCRES-2	61 m (200.2 ft)	Borehole drilled to collect moisture data, soil properties, and borehole geophysics at the confluence of Mortandad Ten Site canyons where surface-based resistivity survey indicates electrically resistive bedrock at depth. Borehole is instrumented with a vector probe. Paired with data collected from MCOBT-4.4 to evaluate lateral changes in resistivity structure in bedrock units beneath Mortandad Canyon.
MCRES-3	61 m (200 ft)	Borehole drilled to collect moisture data, soil properties, and borehole geophysics in Mortandad Canyon east of TW-8 where surface-based resistivity survey indicates resistive bedrock at depth. MCRES-3 is paired with MCRES-4 to evaluate lateral changes in resistivity structure in bedrock units beneath Mortandad Canyon. Borehole plugged and abandoned.
MCRES-4	68.6 m (225 ft)	Borehole drilled to collect moisture data, soil properties, and borehole geophysics in Mortandad Canyon east of TW-8 where surface-based resistivity survey indicates conductive bedrock at depth. MCRES-4 is paired with MCRES-3 to evaluate lateral changes in resistivity structure in bedrock units beneath Mortandad Canyon. Borehole is instrumented with water content and matric potential sensors.
R-28	45.6 (150 ft)	Core collected from the upper 45.6 m (150 ft) of the corehole drilled at the R-28 regional well site were analyzed for moisture data and soil properties. The data were collected to determine if data from a surface-based resistivity survey can be used to predict changes in moisture content with depth. The corehole was plugged and abandoned.

Table 3.4-1
Deviations from Plans for Alluvial Wells,
Characterization Boreholes, Resistivity Boreholes, and Intermediate Wells

Planned	Actual Disposition
Alluvial wells A-3a to A-3f to be drilled along the canyon axis between MCO-8 and MCW-8.1A,B,C	Archeological site restrictions required moving the drilling location . MCA-3 actually installed as two sets of three nested piezometers each. The set MCA-3a,b,c was installed in Mortandad Canyon upcanyon of the confluence with Ten Site Canyon, ~25 ft upcanyon of MCB-7. The set MCA-3d,e,f was installed south of sediment trap #3 and near MCB-9.
Alluvial well MCA-6 to be installed singly in lower Ten Site Canyon	Hole was extended to 154.5-ft depth to accomplish the goals of MCB-15 before the lower interval was plugged to 21.3-ft depth to allow construction of alluvial well MCA-6.
Transect of alluvial wells MCA-7, MCA-8, and MCA-9 proposed across Mortandad Canyon near R-13	All three alluvial explorations were dry to total depth. MCA-8 and MCA-9 were completed as alluvial wells; MCA-7 was plugged and abandoned.
Characterization borehole MCB-3 to be drilled in Mortandad Canyon between MCA-5 and MCO-4	MCB-3 was not drilled because this stretch of Mortandad Canyon is too narrow and heavily vegetated for drilling activity.
Characterization borehole MCB-4 to be drilled in Mortandad Canyon between MCA-5 and MCO-4, immediately north of R-14	MCB-4 was not drilled because this stretch of Mortandad Canyon is too narrow and heavily vegetated for drilling activity.
Characterization borehole MCB-8 to be drilled in Mortandad Canyon between sediment traps #1 and #2	MCB-8 was moved to a location south of sediment trap #1.
Characterization borehole MCB-9 to be drilled in Mortandad Canyon within sediment trap #1	MCB-9 was moved to a location south of sediment trap #3.
Characterization boreholes MCB-10, MCB-11, and MCB-12 to be drilled in Mortandad Canyon in a cluster downcanyon of the sediment traps	Characterization boreholes MCB-10, MCB-11, and MCB-12 were drilled in a north-to-south transect across Mortandad Canyon downcanyon of sediment trap #3.
Characterization borehole MCB-13 to be drilled between MCO-8 and MCW-8.1A,B,C	MCB-13 was not drilled because of archeological site restrictions.
Characterization borehole MCB-14 to be drilled in accessible portion of lower Ten Site Canyon west of MCOI-3	MCB-14 was moved to a location next to sediment trap #1.
Characterization borehole MCB-15 to be installed singly in lower Mortandad Canyon.	MCB-15 was backfilled to 21.3-ft depth and completed as alluvial well MCA-6.
Intermediate well MCOI -3 to be installed in lower Ten Site Canyon with one screen in Cerros del Rio basalt. Projected depth 770 ft. Core to be collected to refusal (~560 ft).	MCOI-3 was not drilled; the objectives set out for MCOI -3 were obtained by drilling R-33 in this locality.
Intermediate well MCOI -5 to be installed near R-15, with one screen in Cerros del Rio basalt. Projected depth 760 ft. Core to be collected to refusal (~500 ft).	Intermediate well MCOI-5 located and completed as planned. Total depth drilled 717 ft. No core was collected because of available core (0–420 ft and 740–751.5 ft) from adjacent R-15 borehole.
Intermediate well MCOI -10 to be installed on the north flank of the mesa south of R-15, on the Qbt 2 bench above the canyon bottom, with one screen in the Cerros del Rio basalt. Projected depth 1000 ft. Core to be collected from 300 to 800 ft depth.	MCOI-10 was moved farther south to the mesa top because of limited space on the Qbt 2 bench. No well was installed at MCOI-10 because the borehole was dry throughout; the hole was plugged and abandoned. Total depth drilled 1050 ft. Core was collected from 300 to 727.3-ft depth.

Notes: Gray shading highlights sample locations required under the "Mortandad Canyon Groundwater Work Plan, Revision 1" (LANL 2004, 82613).
Multiple checks (√) represent number of sampling events in a year. Underlined checks (√) represent samples collected as part of two rounds of snapshot sampling. Underlined Dry (Dry) indicates sample location was dry during the snapshot sampling. Checks without underlining (√) represent samples collected as part of routine surveillance monitoring.

*n/a = Not applicable, well not installed or surface water station not established.

Notes: All values are in mg/kg. All values are maximum detected values. Values in bold exceed the residential SSL. Grey shading indicates a screening value was exceeded for that chemical.

[a] EPA region 6 residential HHMSSL (EPA 2005, 91002).

[b] Pyrene residential SSL is used as a surrogate

[c] SSL based on the soil saturation concentration; not a risk-based value.

[d] Residential SSLs are NMED values (NMED 2006, 92513) unless otherwise noted.

[e] — = Not detected or not analyzed.

[f] Chlordane residential SSL is used as a surrogate.

[g] Isopropylbenzene residential SSL is used as a surrogate.

[h] Naphthalene residential SSL is used as a surrogate.

Notes: All values in ug/L. All surface waters associated with these locations are ephemeral. Bolded concentrations exceed a standard and/or screening level. Grey shading indicates a standard and/or screening value was exceeded for that chemical.

[a] Media code definitions are provided in Table C-2-4.

[b] 20.6.4 NMAC.

[c] — = Not detected or not analyzed.

[d] 20.6.2 NMAC.

[e] EPA 2005, 91002.

[f] EPA MCL for free cyanide.

[g] EPA 2005, 91002 only listed for chemicals without a standard or MCL.

[h] Perchlorate-revised value.

[i] EPA region 9 PRG (EPA 2004, 93663).

All values in ug/L. Bolded concentrations exceed a standard and/or screening level. Grey shading indicates a standard and/or screening value was exceeded for that chemical. All surface waters associated with these locations are ephemeral.

[a] Media code definitions are provided in Table C-2-4.

[b] 20.6.4 NMAC.

[c] — = Not detected or not analyzed.

[d] 20.6.2 NMAC.

[e] EPA MCL for free cyanide.

[f] EPA 2005, 91002.

[g] EPA 2005, 91002 only listed for chemicals without a standard or MCL.

[h] Perchlorate-revised value.

[i] EPA region 9 PRG (EPA 2004, 93663).

Table 8.1-1
Field Studies in Mortandad Canyon Watershed As Implemented

Assay Type	Reach	Rationale for Reach Selection Based on HQ
Soil COPECs		
Earthworm toxicity, plant toxicity, sediment characterization	E-1FW	Plant: high chromium, vanadium (+ other inorganic chemicals) Worm: high chromium, high copper
	E-1W	Plant: high chromium, vanadium Worm: high chromium
	E-1E	Plant: high chromium, high silver Worm: high chromium, high mercury, high Am-241, high Pu-239
	TS-1C	Plant: high selenium, vanadium Worm: di-n-butyl phthalate
	TS-2C	Plant: high silver, high vanadium Worm: moderate chromium, moderate mercury
	M-2W	Plant: lower inorganic chemicals Worm: moderate chromium, moderate mercury, high Am-241, Pu-238, and Pu-239 High perchlorate
	M-4	Plant: high silver, lower other inorganic chemicals Worm: lower chromium, lower mercury Moderate perchlorate
	LA-BKG	Background location
General small mammal trapping, sediment characterization	E-1W	Moderate arsenic and manganese
	M-2W	High thallium, Aroclor-1260 for potential risk to Mexican spotted owl High perchlorate
	M-3	Low arsenic, no other small mammal COPECs Low perchlorate
	LA-BKG	Background location
Shrew trapping, sediment characterization	E-1W	100% wet, high arsenic, high thallium
	LA-BKG	Background location
Plant diversity	E-1FW	Correlate to plant toxicity
	E-1W	Correlate to mammal trapping and plant toxicity
	E-1E	Correlate to plant toxicity
	TS-1C	Correlate to plant toxicity
	TS-2C	Correlate to plant toxicity
	M-2W	Correlate to mammal trapping and plant toxicity High perchlorate
	M-3	Correlate to mammal trapping and plant toxicity
	M-4	Correlate to plant toxicity
	LA-BKG	Background location
Additional nest boxes	E-1FW	Robin: moderate copper, vanadium, PCBs Swallow: no COPECs
	E-1W	Robin: high vanadium, lower zinc Swallow: High aluminum, moderate vanadium, lower copper and zinc Kestrel: no COPECs

Table 8.1-1 (continued)

Assay Type	Reach	Rationale for Reach Selection Based on HQ
	E-1E (bench above reach)	Robin: high mercury, moderate copper, lead Swallow: low zinc Kestrel: no COPECs but total hazard index (HI)=2 and Cs-137 HQ=0.8
	TS-1C	Swallow: high vanadium, zinc Kestrel: no COPECs but total HI=1.2 Robin: highest organic HQ (di-n-butyl phthalate)
	M-1E	Robin: high vanadium Swallow: high aluminum and vanadium, lower zinc Kestrel: no COPECs
	M-2W (bench above reach)	Robin: lower lead, mercury, zinc, PCBs Swallow: low zinc Kestrel: no COPECs but total HI=1.2 High perchlorate
	M-2E (bench above reach)	Robin: moderate mercury Swallow: low zinc Kestrel: no COPECs Moderate perchlorate
	TS-1E	Add to existing network in area of higher contamination
Sediment/Water COPECs		
Aquatic Toxicity and rapid bioassessment protocol	E-1W	High barium, PCBs, DDT for aquatic community
	E-1E	No aquatic community COPECs
	M-1W	Chlordane and DDT COPECs for aquatic community
	M-2W	No aquatic community COPECs Low perchlorate
	TS-1C	High PCBs and anthracene for aquatic community
	TS-1E	High PCBs, anthracene, and copper for aquatic community
	TS-2C	High silver for aquatic community Moderate PCBs and dibenz(a,h)anthracene for aquatic community
	LA-BKG	Background location. Collect sediment and water for toxicity testing, not used for rapid bioassessment protocol
Algal toxicity tests	M-1W	Included to collocate with aquatic toxicity tests
	M-2W	sampled at gaging station E200; location with high HQs for algae for radium-226 and americium-241
	E-1W	Just downcanyon from gaging station E196, location with high HQs for algae for radium-226
	E-1E	Upcanyon of high HQ at gaging station E200 for algae for radium-226 and americium-241
	TS-1C	Included to collocate with aquatic toxicity tests
	TS-1E	Included to collocate with aquatic toxicity tests
	TS-2C	Included to collocate with aquatic toxicity tests
	LA-BKG	Background location

Table 8.1-2
Number of Each Species Collected for Analysis in Each Reach in the Mortandad Watershed

Reach	M-3E	M-2W	E-1W	LA-BKG
Deer Mouse (*Peromyscus maniculatus*)	23	10	8	18
Mexican Wood rat (*Neotoma mexicana*)	4	4	2	0
Brush Mouse (*Peromyscus boylii*)	0	17	7	0
Long-tailed Vole (*Microtus longicaudus*)	0	0	1	5
Pinyon Mouse (*Peromyscus truei*)	0	0	0	2
Western Harvest Mouse (*Reithrodontomys megalotis*)	10	0	0	0
Montane Shrew (*Sorex spp*)	0	0	4	6

Table 8.1-12
Estimate Risk to the Occult Myotis Little Brown Bat
from Ingestion of COPECs in the Tissues of Insects Collected from Nest Boxes

COPEC	Maximum Detected Concentration in Insect Tissue in Nest Box (mg/kg fresh insect)	Mammalian Sediment TRV (mg COPEC/kg bw/day)	Bat Food Ingestion Rate (kgfresh food/kg bird/d)	Food ESL (in mg/kg or pCi/g)	HQ
Aluminum	250	pH dependent	0.410	n/a*	n/a
Arsenic	1.4	1.04	0.410	3	0.55

*n/a = Not applicable.

Table 8.1-13
Estimate of Risk to the Red Fox from Ingestion of COPECs in the Tissues of Small Mammals

COPEC	Measured Whole Animal Concentration	Mammalian TRV (mg/kg/d)	Fox Food Ingestion Rate (kg food fresh weight/kg bird/d)	ESL (in mg/kg)	HQ
Aroclor-1260	0.32	13.8	0.14	98	0.003

Table 8.1-14
Lines of Evidence and Rationale for the Mexican Spotted Owl (AE1)

Line of Evidence	Weight of Evidence Criteria	Result
(1) Modeled exposure and literature toxicity information to calculate spatially weighted HQ values using ECORSK.9 (includes consideration of nesting and foraging habitat based on vegetation class coverage)	Medium	Total mean adjusted HI across watershed for owl equals 1.6, indicating a slight potential fro risk (mostly associated with non-canyons contaminants). Mean adjusted HI for reach with known owl nest is 0.2, indicating no potential for risk to owl.
(2) Modeled and measured concentrations in prey species (small mammals)—compare prey COPEC concentrations across gradient and determine division of contaminants between carcass and pelt	Medium	Dose of COPEC ingested had HQ<1.0 for all COPECs when compared to TRV, indicating that the risk through food ingestion was much lower than that predicted by the ESL screening.
(3) Analysis of owl pellets	Low	Results of pellet analysis confirmed that the small mammal prey species captured and used for tissue analysis are the species consumed by the owl, supporting the use of these species in the food chain modeling
(4) Comparison of concentrations in 2005 sediment samples to ESLs	Low	Screening of 2005 sediment data against ESLs resulted in addtion of bis (2ethylhexyl) phthalate as a new COPEC for this receptor

Table 8.1-15
Lines of Evidence and Rationale for Avian and Mammalian Aerial Insectivores (AE6)

Line of Evidence	Weight of Evidence Criteria	Result	Aerial Insectivore Receptors
(1) Nest box study—determine nest success rate by bluebirds along a gradient of COPEC concentrations in the Mortandad Canyon watershed; need to account for other factors known to influence nest success (food, predators, etc.)	Medium (new boxes) High (established boxes)	Percent fledged and percent female nestlings were not different between Mortandad watershed reaches or between Mortandad watershed and other canyons, indicating no effect on population (measured as nest success)	Southwestern willow flycatcher/Violet-green swallow
(2) Nest box study—determine eggshell thickness for bluebirds along a gradient of COPEC concentrations in Mortandad, Effluent, and Ten Site Canyons; need to account for other factors known to influence eggshell thickness (amount of calcium in diet, etc.)	Medium	Egg size (length and weight), and eggshell thickness were not different between Mortandad reaches or between Mortandad and other canyons, indicating no effect on nest success	Southwestern willow flycatcher/Violet-green swallow
(3) Nest box study—compare COPEC concentrations in eggs within Mortandad Canyon watershed and also compare concentrations with “reference” locations	Medium-low	Concentrations of metals in eggs did not correlate with concentrations of metals in soil, indicating soil is not a source of bioaccumulation into eggs	Southwestern willow flycatcher/Violet-green swallow
(4) Compare the measured concentrations of COPECs in insects with the TRV	Medium	Potential dose through food to Southwestern willow flycatcher and little myotis bat modeled based on measured COPEC concentrations in nest box insects. Copper, mercury, vanadium, and zinc had 1.0<HQ<10 for flycatcher using mean concentrations. Bat had no COPECs with HQ>1.0 using maximum detected concentrations.	Southwestern willow flycatcher/Violet-green swallow Occult little myotis bat
(5) Comparison of concentrations in 2005 sediment and water samples to ESLs	Low	Only new COPEC to swallow or flycatcher from screening of 2005 sediment samples is bis (2 ethylhexyl) phthalate. No new COPECs for bat. Some existing study design COPECs are now COPECs in additional reaches	Southwestern willow flycatcher/Violet-green swallow Occult little myotis bat
(6) Modeled exposure and literature toxicity information to calculate spatially weighted HQ values using ECORSK.9 (includes consideration of nesting and foraging habitat based on vegetation class coverage)—could be based on a frequency of HQ values greater than 1 for the watershed	Medium	The mean adjusted total HI for the SWF was 6.2, based on mercury, di-n-butyl phthalate, boron, and bis (2ethylhexyl) phthtalate. These values indicate a potential for risk to the flycatcher.	Southwestern willow flycatcher

Table 8.1-16
Lines of Evidence and Rationale for Avian Ground Invertevores (AE2)

Line of Evidence	Weight of Evidence Criteria	Result
(1) Nest box Study-Compare the measured concentrations of COPECs in insects with the TRV for the robin with the invertevore diet	Medium	Substituted calculations with earthworms for this measure
(2) Nest box study—determine nest success rate by bluebirds along a gradient of COPEC concentrations in the Mortandad Canyon watershed; need to account for other factors known to influence nest success (food, predators, etc.)	Medium (new boxes) High (established boxes)	Percent fledged and percent female nestlings were not different between Mortandad watershed reaches or between Mortandad watershed and other canyons, indicating no effect on population (measured as nest success)
(3) Nest box study—determine eggshell thickness for bluebirds along a gradient of COPEC concentrations in Mortandad, Effluent, and Ten Site Canyons; need to account for other factors known to influence eggshell thickness (amount of calcium in diet, etc.)	Medium	Egg size (length and weight), and eggshell thickness were not different between Mortandad watershed reaches or between Mortandad watershed and other canyons, indicating no effect on nest success
(4) Nest box study—compare COPEC concentrations in eggs within Mortandad Canyon watershed and also compare concentrations with "reference" locations	Medium-low	Concentrations of metals in eggs did not correlate with concentrations of metals in soil, indicating soil is not a source of bioaccumulation into eggs
(5) Modeled and measured concentrations in food (earthworm bioaccumulation test)—determine if exposure concentrations differ within the watershed in relation to sediment concentrations; design used a gradient in COPEC concentrations with the Mortandad Canyon watershed and also compared concentrations with "reference" locations	Medium	HQs based on modeled doses from estimated concentrations in earthworms indicated that some COPECs (mercury, bis(2-ethylhexyl)phthalate, di-n-butyl phthalate, and Aroclor-1254) may have potential for ecological risk to avian ground invertevores
(6) Modeled exposure and literature toxicity information to calculate spatially weighted HQ values using ECORSK.9 (includes consideration of nesting and foraging habitat based on vegetation class coverage) for bluebird populations in the watershed; will be based on a frequency of HQ values greater than 1 for the watershed (or assessment population area)	Medium	Western bluebird served as a surrogate for the robin representing avian invertevores in the model. The mean adjusted total HI for the bluebird is 1.2, too low for population level effects.
(7) Field surveys of avian ground invertevore abundance and diversity in the Mortandad Canyon watershed; and also compare abundance/diversity with "reference" locations	Low	Field surveys of Upper Mortandad and Ten Site Canyon had similar diversity indices and most species in both areas were invertevores, no population level effects seen
(8) Comparison of concentrations in 2005 sediment samples to ESLs	Low	Only new COPEC from screening of 2005 sediment samples is bis(2-ethylhexyl)phthalate. Some existing study design COPECs are now COPECs in additional reaches.

Table 8.1-17
Lines of Evidence and Rationale for Mammalian Invertevores and Omnivores (AE3)

Line of Evidence	Weight of Evidence Criteria	Result
(1) Field surveys to determine small mammal reproduction status along gradient of COPEC concentrations in the Mortandad Canyon watershed and also compare reproduction rates with "reference" locations	Medium high	No differences seen in relative population abundance, gender, or body weight between reaches
(2) Modeled and measured concentrations in food (earthworms)—could determine if exposure concentrations differ within the watershed in relation to sediment concentrations; design could use a gradient in COPEC concentrations with the Mortandad Canyon watershed and also compare concentrations with "reference" location	Medium	Modeling of potential risk through food to the shrew or mouse using estimated concentrations in earthworms showed only thallium with an HQ elevated enough to indicate potential for population-level effects. Thallium has a very low TRV and high default TF in model
(3) Modeled exposure and literature toxicity information to calculate spatially weighted HQ values using ECORSK.9 (includes consideration of nesting and foraging habitat based on vegetation class coverage) for deer mouse and shrew populations in the watershed—could be based on a frequency of HQ values greater than 1 for the watershed	Medium	Mean HI exceeded 1 in only 8% of sites across watershed. Dominant COPEC in this model is also thallium
(4) Comparison of concentrations in 2005 sediment samples to ESLs	Low	Screening of 2005 sediment sample data did not show any new COPECs for these receptors

Table 8.1-18
Lines of Evidence and Rationale for Detritivores (AE4)

Line of Evidence	Weight of Evidence Criteria	Result
(1) Toxicity test (earthworm mortality) along gradient of COPEC concentrations in the Los Alamos and Pueblo watershed—compare mortality rates with "reference" locations	High	No differences in earthworm mortality seen between reaches, indicating no effect along COPEC gradient. Weight loss differed between reaches, but did not correlate with COPEC concentration.
(2) The concentration of COPECs in earthworms	Contributor to other AEs	Not measured due to laboratory error
(3) Comparison of concentrations in 2005 sediment samples to ESLs	Low	Screening of 2005 sediment data indicates that hexavalent chromium would be a study design COPEC for this receptor. Existing studies included reaches with this COPEC.

Table 8.1-19
Lines of Evidence and Rationale for Plants (AE5)

Line of Evidence	Weight of Evidence Criteria	Result
1) Toxicity test (seedling germination) along gradient of COPEC concentrations in the Los Alamos and Pueblo watershed and also compare germination rates with "reference" locations	High	No differences in mortality, dry root mass, dry shoot mass, or mean root length. Some differences in wet root length and mean shoot length between reaches, but effect did not match with COPEC concentration
2) Abundance and diversity of plants along gradient of COPEC concentrations in the Mortandad watershed and also compare plant abundance/diversity with "reference" locations	Medium	Plant survey showed differences between reaches, but not attributable to COPEC gradient. Differences attributable to climate factors, and species in all reaches increased since previous survey during dry year.
(3) Comparison of concentrations in 2005 sediment samples to ESLs	Low	Screening of 2005 sediment data indicates that hexavalent chromium would be a study design COPEC for this receptor. Existing studies included reaches with this COPEC.

Table 8.1-20
Lines of Evidence and Rationale for the Aquatic Community (AE7)

Line of Evidence	Weight of Evidence Criteria	Result
(1) Estimates of growth and mortality of aquatic invertebrates based on toxicity tests using *Chironomus tentans* compared with the reference location	High	No significant differences in larval survival or mean dry weight of larvae between reaches, indicating no effect of COPECs on larval survival and growth.
(2) A rapid bioassessment characterization to evaluate habitat ratings at selected locations based on watershed features, riparian vegetation, in-stream features, aquatic vegetation, and benthic substrate; assessment will also include measures of abundance and diversity of aquatic invertebrates through Hess sampling and dip net capture	Medium	Physical aspects of habitat similar between reaches; all rated as marginal using index scores. Chironomids made up majority of biomass in all reaches, supporting their use as toxicity indicator organism.
(3) Comparison of concentrations in 2005 sediment and water samples to ESLs	Low	Screening of 2005 sediment data indicated iron should be a new COPEC for this receptor. Screening of water data also indicated iron should be a new COPEC, and cobalt would be a COPEC at one water location
(4) Algae toxicity test	High	Differences seen between water samples from different reaches attributable to differences in water hardness. Algal cell growth in all samples except TS-1C exceeded negative and positive laboratory control sample growth. Results indicate no impairment of algal cell growth due to COPECs in water.

Notes: Residential SSL values are in mg/kg. Ratios in bold and gray shading show where the SOFnc>1 and the ratio is >0.1.

[a] EPA Region 6 residential SSL (EPA 2005, 91002).

[b] EPA Region 9 residential SSL (epa.gov/region09/waste/sfund/prg/files/04prgtable.pdf).

[c] Pyrene used as surrogate for benzo(g,h,i)perylene. Isopropyltoluene uses isopropylbenzene SSL as surrogate and 2-methylnaphthalene uses naphthalene as surrogate.

[d] Screening value is based on saturation, not risk based.
